Disjunctive Logic Programming is nowadays a mature formalism which has been successfully applied to a variety of practical problems, such as information integration, knowledge representation, planning, diagnosis, optimization and configuration. Although current DLP systems have been extended in many directions, they still miss features which may be helpful towards industrial applications, like the capability of quickly introducing new predefined constructs or of dealing with modules. Indeed, in spite of the fact that a wide literature about modular logic programming is known, code reusability has never been considered as a critical point in Disjunctive Logic Programming. In this work we extend the Disjunctive Logic Programming, under the stable model semantics, with the notion of ‘template’ predicates. A template predicate may be instantiated to an ordinary predicate by means of template atoms, thus allowing to define reusable modules, to define new constructs and aggregates without any syntactic limitation.

Keywords: Disjunctive Logic Programming, Modular Logic Programming, Knowledge Representation

1. Introduction

Disjunctive Logic Programming (DLP) is nowadays a generic term including many language flavors, whose common base is the adoption of the ‘Gelfond-Lifschitz reduct’ [Gelfond and Lifschitz, 1991] as a main tool for defining the underlying semantics. Roughly speaking, Disjunctive Logic Programming dialects are variants of Datalog, where models for a given program (stable models) may be multiple. Most of these languages allow to filter out models by means of constraints or to select among different models by means of weight constraints or similar extensions [Buccafurri \textit{et al.}, 2000; Niemelä \textit{et al.}, 1999; Niemelä, 1999; Simons, 1999; Niemelä \textit{et al.}, 1999; 2000; Marek and Remmel, 2002; Ferraris and Lifschitz, 2005].

After some pioneering work on stable model computation [Bell \textit{et al.}, 1994; Subrahmanian \textit{et al.}, 1995], research in the field produced several, mature, implemented systems featuring clear semantics and efficient program evaluation [Seipel and Thöne, 1994; Babovich, since 2002; Chen and Warren, 1996; Cholewiński \textit{et al.}, 1996; Aravindan \textit{et al.}, 1997; Rao \textit{et al.}, 1997; McCain and Turner, 1998; Cholewiński \textit{et al.}, 1999; Egly \textit{et al.}, 2000; East and Truszczynski, 2000; Anger \textit{et al.}, 2001; East and Truszczynski, 2001; Leone \textit{et al.}, 2005b; Lierler and Maratea, 2004; Lin and Zhao, 2004; Janhunen and Niemelä, 2004; Lierler, 2005].

DLP under the stable model semantics has recently found a number of promising applications: several tasks in information integration and knowledge management require complex reasoning capabilities, which are explored, for instance, in the INFOMIX and ICONS projects (funded by the European Commission) [Leone \textit{et al.}, 2005a; ICONS, since 2001].

It is very likely that this new generation of DLP applications require the introduction of repetitive pieces of standard code. Indeed, a major need of complex and huge DLP applications such as [Nogueira \textit{et al.}, 2001] is dealing efficiently with large pieces of such a code and with complex data structures, more sophisticated than the simple, native ASP data types.

Indeed, the non-monotonic reasoning community has continuously produced, in the past, several extensions of nonmonotonic logic languages, aimed
at improving readability and easy programming through the introduction of new constructs, employed in order to specify classes of constraints, search spaces, data structures, new forms of reasoning, new special predicates [Cadoli et al., 1999; Eiter et al., 1997a; Kuper, 1990], such as aggregate predicates [Calimeri et al., 2005]. Nonetheless, code reusability has never been considered as a priority in the Answer Set Programming/DLP field, despite the fact that modular logic programming has been widely studied in the general case [Bugliesi et al., 1994; Eiter et al., 1997b].

The language $\text{DLP}^T$ we propose here has two purposes. First, $\text{DLP}^T$ moves the DLP field towards industrial applications, where code reusability is a crucial issue. Second, $\text{DLP}^T$ aims at minimizing developing times in DLP system prototyping. DLP systems developers wishing to introduce new constructs are enabled to fast prototype their languages, make their language features quickly available to the scientific community, and successively concentrate on efficient (and long lasting) implementations. To this end, it is necessary a sound specification language for new DLP constructs. DLP itself proves to fit very well for this purpose. The proposed framework introduces the concept of ‘template’ predicate, whose definition can be exploited whenever needed through binding to usual predicates.

Template predicates can be seen as a way to define intensional predicates by means of a subprogram, where the subprogram is generic and reusable. This eases coding and improves readability and compactness of DLP programs:

**Example 1** The following template definition

```
#template max[p(1)](1)
{
 exceeded(X) :- p(X), p(Y), Y > X.
 max(X) :- p(X), not exceeded(X).
}
```

introduces a generic template program, defining the predicate $\text{max}$, intended to compute the maximum value over the domain of a generic unary predicate $p$. A template definition may be instantiated as many times as necessary, through *template atoms*, like in the following sample program

```
:- max[weight(*)](M), M > 100. (a)
:- max[student(Sex,$,*)](M), M > 25. (b)
```

Template definitions may be unified with a template atom in many ways. The above program contains two invocations: a *plain* invocation (a), and a *compound* invocation (b). The latter allows to employ the definition of the template predicate $\text{max}$ on a ternary predicate, discarding the second attribute of $\text{student}$, and grouping by values of the first attribute.

The operational semantics of the language is defined through a suitable algorithm (actually, a *pseudo*-algorithm, as we will see in Section 4) which is able to produce, from a set of nonrecursive template definitions and a $\text{DLP}^T$ program, an equivalent DLP program. There are some important theoretical questions to be addressed, such as the termination of the algorithm, and the expressiveness of the $\text{DLP}^T$ language. Indeed, we prove that it is guaranteed that $\text{DLP}^T$ program encodings are as efficient as plain DLP encodings, since unfolded programs are just polynomially larger with respect to the originating program. The $\text{DLP}^T$ language has been successfully implemented and tested on top of the DLV system [Faber et al., 2001]. Anyway, the proposed paradigm does not rely at all on DLV special features, and is easily generalizable. In sum, benefits of the $\text{DLP}^T$ language are: improved declarativity and succinctness of the code; code reusability and possibility to collect templates within libraries; capability to quickly introduce new, predefined constructs; fast language prototyping.

The paper is structured as follows:

- Section 2 briefly gives syntax and semantics of DLP and syntax of the language $\text{DLP}^T$.
- The features of $\text{DLP}^T$ are illustrated in Section 3, with the help of some examples.
- Section 4 formally introduces the semantics of $\text{DLP}^T$.
- Theoretical properties of $\text{DLP}^T$ are discussed in Section 5.
- An implementation of the $\text{DLP}^T$ language on top of a suitable DLP solver is presented in Section 6.
- Eventually, in section 7, conclusions are drawn.
2. Syntax of the DLP² language

We provide here the syntax of DLP². But first, we give a survey on formal syntax and semantics of DLP.

2.1. Disjunctive Logic Programming

The flavor of DLP we will consider is basically consisting in Disjunctive Datalog enriched with weak constraints. For further background the reader can refer to [Eiter et al., 2000; Gelfond and Lifschitz, 1991]. In addition, in [Apt and Bol, 1994; Dix, 1995] more comprehensive surveys on the semantics of disjunction and negation are given.

2.1.1. DLP Syntax

A (standard) term is either a variable or a constant. Usually, strings starting with uppercase letters denote variables, while those starting with lowercase letters denote constants, such as X and x, respectively.

An atom is an expression \( p(t_1, \ldots, t_n) \), where \( p \) is a predicate of arity \( n \) and \( t_1, \ldots, t_n \) are terms, such as edge \((a, X)\) or \( p(X) \). A classical literal \( l \) is either an atom \( p \) (in this case, it is positive), or a (strongly) negated atom \( \neg p \) (in this case, it is negative). A negation as failure (NAF) literal \( \ell \) is of the form \( l \) or \( \neg l \), where \( l \) is a classical literal; in the former case \( \ell \) is positive, and in the latter case negative. Unless stated otherwise, by literal a NAF literal is meant.

Given a classical literal \( l \), its complementary literal \( \neg l \) is defined as \( \neg p \) if \( l = p \) and \( p \) if \( l = \neg p \). A set \( L \) of literals is said to be consistent if, for every literal \( l \in L \), its complementary literal is not contained in \( L \).

A disjunctive rule (rule, for short) \( r \) is a formula 
\[
\forall \{a_1, \ldots, a_n\} \leftarrow b_1, \ldots, b_k, \text{not } b_{k+1}, \ldots, \text{not } b_m \quad (1)
\]
where \( a_1, \ldots, a_n, b_1, \ldots, b_k \) are classical literals and \( n \geq 0, m \geq k \geq 0 \). The disjunction \( a_1 \vee \cdots \vee a_n \) is said to be the head of \( r \), while the conjunction \( b_1, \ldots, b_k \) is the body of \( r \). A rule without head literals (i.e. \( n = 0 \)) is usually referred to as an integrity constraint. A rule having precisely one head literal (i.e. \( n = 1 \)) is called a normal rule. If the body of \( r \) is empty (i.e. \( k = m = 0 \)), \( r \) is called fact, and usually the “\( \neg \)” sign is omitted.

For any set \( L \) of classical literals, \( L = \{ \text{not } l \mid l \in L \} \) is denoted. If \( r \) is a rule of form (1), then \( H(r) = \{a_1, \ldots, a_n\} \) is the set of the literals in the head and \( B(r) = B^+(r) \cup B^-(r) \) is the set of the body literals, where \( B^+(r) \) (the positive body) is \( \{b_1, \ldots, b_k\} \) and \( B^-(r) \) (the negative body) is \( \{b_{k+1}, \ldots, b_m\} \).

A DLP program (alternatively, disjunctive datalog program) \( P \) is a finite set of rules. A not-free program \( P \) (i.e., such that \( \forall r \in P : B^-(r) = \emptyset \)) is called positive. In positive programs negation as failure (not) does not occur, while strong negation (\( \neg \)) may be present. A \( v \)-free program \( P \) (i.e., such that \( \forall r \in P : |H(r)| \leq 1 \)) is called a datalog program (or normal logic program). A term (an atom, a rule, a program, etc.) is ground, if no variable appears in it. A ground program is also called a propositional program.

Usually, we simply refer to programs, if we want to point out that they are not restricted to be positive, normal or ground.

Weak constraints. Weak constraints (see [Buccafurri et al., 2000]) are defined as a variant of integrity constraints. In order to differentiate clearly between them, for weak constraints the symbol ‘\( \sim \)’ is adopted instead of ‘\( \neg \)’. Additionally, a weight and a priority level (or layer) inducing a partial order of the weak constraints are specified explicitly.

Formally, a weak constraint \( wc \) is an expression of the form
\[
\sim b_1, \ldots, b_k, \text{not } b_{k+1}, \ldots, \text{not } b_m \cdot [w : l]
\]
where for \( m \geq k \geq 0, b_1, \ldots, b_m \) are classical literals, while \( w \) (the weight) and \( l \) (the level, or layer) are positive integer constants or variables. For convenience, \( w \) and/or \( l \) might be omitted and are set to 1 in this case.

The sets \( B(wc), B^+(wc) \), and \( B^-(wc) \) of a weak constraint \( wc \) are defined in the same way as for regular integrity constraints.

2.1.2. DLP Semantics

The most widely accepted semantics for DLP is the Stable Model Semantics proposed by Gelfond and Lifschitz in 1991. According to this semantics, a program may have several alternative stable models (but possibly none), each corresponding to a possible view of the world.

The semantics provided in this section is a generalization of the original semantics proposed for weak constraints in [Buccafurri et al., 2000], as seen in [Leone et al., 2005b].
**Herbrand Universe.** For any program $\mathcal{P}$, let $U_\mathcal{P}$ (the Herbrand Universe) be the set of all constants appearing in $\mathcal{P}$. In case no constant appears in $\mathcal{P}$, an arbitrary constant $\psi$ is added to $U_\mathcal{P}$.

**Herbrand Literal Base.** For any program $\mathcal{P}$, let $B_\mathcal{P}$ be the set of all ground (classical) literals constructible from the predicate symbols appearing in $\mathcal{P}$ and the constants of $U_\mathcal{P}$ (note that, for each atom $p$, $B_\mathcal{P}$ contains also the strongly negated literal $\neg p$).

**Ground Instantiation.** For any rule $r$, $\text{Ground}(r)$ denotes the set of rules obtained by applying all possible substitutions $\sigma$ from the variables in $r$ to elements of $U_\mathcal{P}$. In a similar way, given a weak constraint $w$, $\text{Ground}(w)$ denotes the set of weak constraints obtained by applying all possible substitutions $\sigma$ from the variables in $w$ to elements of $U_\mathcal{P}$. For any program $\mathcal{P}$, $\text{Ground}(\mathcal{P})$ denotes the set $\text{GroundRules}(\mathcal{P}) \cup \text{GroundWC}(\mathcal{P})$, where

$$\text{GroundRules}(\mathcal{P}) = \bigcup_{r \in \text{Rules}(\mathcal{P})} \text{Ground}(r)$$

and

$$\text{GroundWC}(\mathcal{P}) = \bigcup_{w \in \text{WC}(\mathcal{P})} \text{Ground}(w).$$

For propositional programs, $\mathcal{P} = \text{Ground}(\mathcal{P})$ holds.

**Stable Models.** For every program $\mathcal{P}$, we define its stable models using its ground instantiation $\text{Ground}(\mathcal{P})$ in three steps: first we define the stable models of positive disjunctive datalog programs, then we give a reduction of disjunctive datalog programs containing negation as failure to positive ones and use it to define stable models of arbitrary disjunctive datalog programs, possibly containing negation as failure. Finally, we specify the way how weak constraints affect the semantics, defining the semantics of general programs.

An interpretation $I$ is a set of ground classical literals, i.e. $I \subseteq B_\mathcal{P}$ w.r.t. a program $\mathcal{P}$. A consistent interpretation $I \subseteq B_\mathcal{P}$ is called closed under $\mathcal{P}$ (where $\mathcal{P}$ is a positive disjunctive datalog program), if, for every $r \in \text{Ground}(\mathcal{P})$, $I(r) \cap I \neq \emptyset$ whenever $B(r) \subseteq I$. An interpretation $I \subseteq B_\mathcal{P}$ is a stable model for a positive disjunctive datalog program $\mathcal{P}$, if it is minimal (under set inclusion) among all interpretations that are closed under $\mathcal{P}$.

**Example 2** The positive program

$$\mathcal{P}_1 = \{ a \lor \neg b \lor c \}$$

has the stable models $\{a\}$, $\{-b\}$, and $\{c\}$. Its extension

$$\mathcal{P}_2 = \{ a \lor \neg b \lor c ., \neg a \}$$

has the stable models $\{-b\}$ and $\{c\}$. Finally, the positive program

$$\mathcal{P}_3 = \{ a \lor \neg b \lor c ., \neg a , \neg b \lor c , c \leftarrow \neg b \}$$

has the single stable model the set $\{-b, c\}$.

The reduct or Gelfond-Lifschitz transform of a ground program $\mathcal{P}$ w.r.t. a set $I \subseteq B_\mathcal{P}$ is the positive ground program $\mathcal{P}^I$, obtained from $\mathcal{P}$ by

- deleting all rules $r \in \mathcal{P}$ for which $B^-(r) \cap I \neq \emptyset$ holds;
- deleting the negative body from the remaining rules.

A stable model of a program $\mathcal{P}$ is a set $I \subseteq B_\mathcal{P}$ such that $I$ is a stable model of $\text{Ground}(\mathcal{P})^I$.

**Example 3** Given the general program $\mathcal{P}_4$:

$$a \lor \neg b \leftarrow c.$$  
$$\neg b \leftarrow \text{not a, not } c.$$  
$$a \lor c \leftarrow \text{not } \neg b.$$

and the interpretation $I = \{\neg b\}$, the reduct $\mathcal{P}_4^I$ is $\{ a \lor \neg b \leftarrow c ., \neg b \}$. It is easy to see that $I$ is a stable model of $\mathcal{P}_4^I$, and for this reason it is also a stable model of $\mathcal{P}_4$.

Now consider the interpretation $J = \{a\}$. The reduct $\mathcal{P}_4^J$ is $\{ a \lor \neg b \leftarrow c ., a \lor c \}$ and it can be easily verified that $J$ is a stable model of $\mathcal{P}_4^J$, so it is also stable model of $\mathcal{P}_4$.

If, on the other hand, we take $K = \{c\}$, the reduct $\mathcal{P}_4^K$ is equal to $\mathcal{P}_4^J$, but $K$ is not stable model of $\mathcal{P}_4^J$; for the rule $r : a \lor \neg b \leftarrow c$, $B(r) \subseteq K$ holds, but $H(r) \cap K \neq \emptyset$ does not. Indeed, it can be verified that $I$ and $J$ are the only stable models of $\mathcal{P}_4$.

---

1Note that we only consider consistent stable models, while in [Gelfond and Lifschitz, 1991] also the inconsistent set of all possible literals can be a valid stable models.
Given a ground program \( P \) with a set of weak constraints \( WC(P) \), we are interested in the stable models of \( Rules(P) \) which minimize the sum of weights of the violated (unsatisfied) weak constraints in the highest priority level\(^2\), and among them those which minimize the sum of weights of the violated weak constraints in the next lower level, etc. Formally, this is expressed by an objective function \( H^P(A) \) for \( P \) and a stable model \( A \) as follows, using an auxiliary function \( f_P \) which maps leveled weights to weights without levels:

\[
\begin{align*}
 f_P(1) &= 1, \\
 f_P(n) &= f_P(n-1) \cdot |WC(P)| \cdot w^P_{\text{max}} + 1, \quad n > 1, \\
 H^P(A) &= \sum_{i=1}^{P} f_P(i) \cdot \sum_{w \in N^P_i(A)} \text{weight}(w),
\end{align*}
\]

where \( w^P_{\text{max}} \) and \( P^P_{\text{max}} \) denote the maximum weight and maximum level over the weak constraints in \( P \), respectively; \( N^P_i(A) \) denotes the set of the weak constraints in level \( i \) that are violated by \( A \), and \( \text{weight}(w) \) denotes the weight of the weak constraint \( w \). Note that \( |WC(P)| \cdot w^P_{\text{max}} + 1 \) is greater than the sum of all weights in the program, and therefore guaranteed to be greater than the sum of weights of any single level.

Intuitively, the function \( f_P \) handles priority levels. It guarantees that the violation of a single constraint of priority level \( i \) is more “expensive” than the violation of all weak constraints of the lower levels (i.e., all levels \( < i \)).

For a program \( P \) (possibly with weak constraints), a set \( A \) is an (optimal) stable model of \( P \) if and only if (1) \( A \) is a stable model of \( Rules(P) \) and (2) \( H^P(A) \) is minimal over all the stable models of \( Rules(P) \).

**Example 4** Consider the following program \( P_{wc} \), which contains three weak constraints:

\[
\begin{align*}
 a \vee b, \\
 b \vee c, \\
 d \vee \neg d &\leftarrow a, c, \\
 \neg b &\leftarrow [1 : 2], \\
 \neg a, \neg d &\leftarrow [4 : 1], \\
 \neg c, d &\leftarrow [3 : 1].
\end{align*}
\]

\( Rules(P_{wc}) \) admits three stable models: \( A_1 = \{a, c, d\} \), \( A_2 = \{a, c, \neg d\} \), and \( A_3 = \{b\} \). We have:

\[
\begin{align*}
 H^P_{wc}(A_1) &= 3, \quad H^P_{wc}(A_2) &= 4, \quad H^P_{wc}(A_3) &= 13.
\end{align*}
\]

Thus, the unique (optimal) stable model is \( \{a, c, d\} \) with weight 3 in level 1 and weight 0 in level 2.

\(^2\)Higher values for weights and priority levels mark weak constraints of higher importance. E.g., the most important constraints are those having the highest weight among those with the highest priority level.

### 2.2. DLP\(^T\)

A DLP\(^T\) program is a DLP program where (possibly negated) template atoms may appear in rules and constraints. Definition of template atoms is next provided.

**Definition 1** A template definition \( D \) consists of:

- a template header,

\[
\#\text{template } n_D[f_1(b_1), \ldots, f_n(b_n)](b_{n+1})
\]

where \( b_1, \ldots, b_{n+1} \) are (nonnegative) integer values, and \( f_1, \ldots, f_n \) are predicate names (formal predicates, from now on). \( n_D \) is called template name;

- an associated DLP\(^T\) subprogram enclosed in curly braces; \( n_D \) may be used within the subprogram as predicate of arity \( b_{n+1} \), whereas the predicates \( f_1, \ldots, f_n \) are intended to be of arity \( b_1, \ldots, b_n \), respectively. At least a rule having \( n_D \) within its head must appear in the subprogram.

**Example 5** Beside the one introduced in Example 1, another valid template definition is the following:

\[
\#\text{template subset}[p(1)](1)
\]

\[
\{
\text{subset}(X) \vee \neg \text{subset}(X) : - p(X).
\}
\]

Intuitively, this defines a subset of the predicate ‘p’; such a subset is non-deterministically chosen by means of disjunction.

**Definition 2** A template atom \( t \) is of the form:

\[
n_t[p_1(X_1), \ldots, p_n(X_n)](A)
\]

where \( p_1, \ldots, p_n \) are predicate names (namely, actual predicates), and \( n_t \) is a template name. \( X_1, \ldots, X_n \) are lists of special terms (referred in the following as special lists of terms), where \( A \) is a list of standard terms.

A special term is either a standard term, or a dollar (‘$’) symbol (from now on, projection term) or a star (‘*’) symbol (from now on, parameter term). \( p_1(X_1), \ldots, p_n(X_n) \) are called special atoms. \( A \) is called output list.

Given a template atom \( t \), let \( D(t) \) be the corresponding template definition having the same template name. It is assumed there is a unique definition for each template name.
Example 6 Some template atoms are

\[
\text{max}[\text{company}($,\text{State},*)](\text{Income}). \\
\text{subset}[\text{node}(*)](X).
\]

Template atoms may “instantiate” template definitions as many times as necessary.

Example 7 The following short piece of program contains multiple instantiation of the ‘max’ template, whose definition has been introduced in Example 1:

\[
:\text{- max}[\text{weight}(*)](M), M > 100. \\
:\text{- max}[\text{student}(\text{Sex},$,*,)](M), M > 25.
\]

Looking at Example 6 and Example 7, we can get some intuitions on (‘$’ and ‘*’ symbols). Basically, projection terms (‘$’ symbols) are intended to indicate which attributes, among those belonging to an actual predicate, have to be ignored. A standard term (a constant or a variable) within an actual atom indicates a ‘group-by’ attribute, whereas parameter terms (‘*’ symbols) indicate which attributes have to be considered as parameters.

Thus, the intuitive meaning of the first template atom of example 6 is to compute the companies with the maximum value of the ‘income’ attribute (the third attribute of the \text{company} predicate), grouped by the ‘state’ attribute (the second one), ignoring the first attribute. The computed values of \text{Income} are returned through the output list.

Example 8 Given a database by means of facts like

\[
\text{emp} \text{companyA}(“Jones”,30000,35,“Accounting”). \\
[...]
\text{emp} \text{companyB}(“Miller”,34000,29,“Marketing”).
\]

the following single-rule program

\[
\text{emp} \text{companyAB}(\text{Name}) : - \\
\text{intersection}[\text{emp} \text{companyA}](*,$,*,), \\
\text{emp} \text{companyB}(*,$,*,)](\text{Name}).
\]

computes the employees working for both company A and company B. It exploits the template ‘intersection’, defined in Section 3, and again shows how ‘$’ and ‘*’ symbols can be used. The last three attributes (name, salary, department) are thus ignored, by meaning of ‘$’ symbols, while the first (name) is intended as parameter, by meaning of ‘*’ symbol.

3. Knowledge Representation by DLP\textsuperscript{T}

In this section we show by examples the main advantages of template programming. Examples point out the provision of a succinct, elegant and easy-to-use way for quickly introducing new constructs through the DLP\textsuperscript{T} language.

\textbf{Aggregates.} Aggregate predicates [Ross and Sagiv, 1997], allow to represent properties over sets of elements. Aggregates or similar special predicates have been already studied and implemented in several DLP solvers [Dell’Armi \textit{et al.}, 2003; Simons, 2000]: the next example shows how to fast prototype aggregate semantics without taking into account of the efficiency of a built-in implementation. Here we take advantage of the template predicate \text{max}, defined in Example 1. The next template predicate defines a general program to count distinct values of a predicate \text{p}, given an order relation \text{succ} defined on the domain of \text{p}. We assume the domain of integers is bounded to some finite value.

\[
\#\text{template count}[\text{p}(1),\text{succ}(2)](1) \\
\{ \\
\text{partialCount}(0,0). \\
\text{partialCount}(I,V) :- \text{not p}(Y), I=Y+1, \\
\text{partialCount}(Y,V). \\
\text{partialCount}(I,V2) :- p(Y), I=Y+1, \\
\text{partialCount}(Y,V), \text{succ}(V,V2). \\
\text{partialCount}(I,V2) :- p(Y), I=Y+1, \\
\text{partialCount}(Y,V), \text{max}[\text{succ}(*,*)](V2). \\
\text{count}(M) :- \text{max}[\text{partialCount}(*,*)](M).
\}
\]

The above template definition is conceived in order to count, in a iterative-like way, values of the \text{p} predicate through the \text{partialCount} predicate. A ground atom \text{partialCount}(i,a) means that at the stage \text{i}, the constant \text{a} has been counted up. The predicate \text{count} takes the value which has been counted at the highest (i.e. the last) stage value. The above program is somehow involved
and shows how difficult could be to simulate aggregate constructs in Disjunctive Logic Programming. Anyway, the use of templates allows to write it once, and reuse it as many times as necessary. It is worth noting how \(	ext{max}\) is employed over the binary predicate \(\text{partialCount}\), instead of an unary one. Indeed, the ‘\$’ and ‘\*’ symbols are employed to project out the first argument of \(\text{partialCount}\). The last rule is equivalent to the piece of code:

\[
\text{partialCount}'(X) :- \text{partialCount}(_,X).
\]

\[
\text{count}(M) :- \text{max}[\text{partialCount}'(*)](M).
\]

**Definition of ad hoc search spaces.** Template definitions can be employed to introduce and reuse constructs defining the most common search spaces. This improves declarativity of DLP programs to a larger extent. The next two examples show how to define a predicate \(\text{subset}\) and a predicate \(\text{permutation}\), ranging, respectively, over subsets and permutations of the domain of a given predicate \(p\). Such kind of constructs enriching plain Datalog languages have been proposed, for instance, in [Laenens et al., 1990; Cadoli and Schaerf, 2001].

```datalog
#template subset[p(1)](1)
{ 
  subset(X) v -subset(X) :- p(X).
}

#template permutation[p(1)](2).
{ 
  permutation(X,N) v npermutation(X,N) :- p(X), #int(N), count[p(*),>(*,*)](N1), N<=N1.
  :- permutation(X,A),permutation(Z,A), Z <> X.
  :- permutation(X,A),permutation(X,B), A <> B.
  covered(X) :- permutation(X,A).
  :- p(X), not covered(X).
}
```

The explanation of the \(\text{subset}\) template predicate (already appeared in Example 5 is quite straightforward. As for the \(\text{permutation}\) definition, a ground atom \(\text{permutation}(x,i)\) tells that the element \(x\) (taken from the domain of \(p\)), is in position \(i\) within the currently guessed permutation. The rest of the template subprogram forces permutations properties to be met.

Next we show how \(\text{count}\) and \(\text{subset}\) can be exploited to succinctly encode the \(k\)-clique problem [Garey and Johnson, 1979], i.e., given a graph \(G\) (represented by predicates \(\text{node}\) and \(\text{edge}\)), find if there exists a complete subgraph containing at least \(k\) nodes (we consider here the 5-clique problem):

\[
\text{in_clique}(X) :- \text{subset}[\text{node}(*)](X).
\]

\[
\text{:- count[\text{in_clique}(*),>(*,*)](K), K < 5.}
\]

\[
\text{:- in_clique}(X),\text{in_clique}(Y), X <> Y, \\
\text{not edge}(X,Y).
\]

The first rule of this example guesses a clique from a subset of nodes. The first constraint forces a candidate clique to be at least of 5 nodes, while the last forces a candidate clique to be strongly connected. The \(\text{permutation}\) template can be employed, for instance, to encode the Hamiltonian Path problem: given a graph \(G\), find a path visiting each node of \(G\) exactly once:

\[
\text{path}(X,N) :- \text{permutation}[\text{node}(*)](X,N).
\]

\[
\text{:- path}(X,M), \text{path}(Y,N), \text{not edge}(X,Y), \\
M = N+1.
\]

The following \(\text{any}\) template may be employed in order to (non-deterministically) select exactly one value from the domain of a predicate \(p\). It is built on top of the \(\text{subset}\) predicate.

```datalog
#template any[p(1)](1)
{ 
  any (X) :- subset[p(*)](X).
  :- any(X), any(Y), X <> Y.
  :- p(X), not any(X).
}
```

**Handling of complex data structures.** DLPT can be fruitfully employed to introduce operations over complex data structures, such as sets, dates, trees, etc.

**Sets:** Extending Datalog with Set programming is another matter of interest for the DLP field. This topic has been already discussed (e.g. in [Leone and Rullo, 1993; Kuper, 1990]), proposing some formalisms aiming at introducing a suitable se-
mantics with sets. It is fairly quick to introduce
set primitives using \textsc{dlp} \textsuperscript{T}; a set \( S \) is modeled
through the domain of a given unary predicate \( s \).
Intuitive constructs like \texttt{intersection}, \texttt{union}, or
symmetric difference, can be modeled as follows.
\texttt{#template intersection\[a(1),b(1)\](1)}.
\{intersection \((X)\) :- \( a(X)\), \( b(X) \).\}
\texttt{#template union\[a(1),b(1)\](1)}.
\{union \((X)\) :- \( a(X) \).
union \((X)\) :- \( b(X) \).\}
\texttt{#template symmetricdifference\[a(1),b(1)\](1)}.
\{symmetricdifference \((X)\) :- union\[a(*),b(*)\](X),
not intersection\[a(*),b(*)\](X).\}
\texttt{Dates:} managing time and date data types is an-
other important issue in engineering applications
of \textsc{dlp}. For instance, in [Ianni \textit{et al.}, 2003], it is very
important to reason on compound records containing
date values. The following template shows how to compare dates represented
through a ternary relation \((\text{day, month, year})\).
\{before\[date1(3),date2(3)\](6) \}
\{before\((D,M,Y,D1,M1,Y1)\) :- date1\((D,M,Y)\),
date2\((D1,M1,Y1)\), \( Y=Y1 \).
before\((D,M,Y,D1,M1,Y1)\) :- date1\((D,M,Y)\),
date2\((D1,M1,Y1)\), \( Y=Y1\), \( M>M1 \).
before\((D,M,Y,D1,M1,Y1)\) :- date1\((D,M,Y)\),
date2\((D1,M1,Y1)\), \( Y=Y1\), \( M=M1\), \( D<D1 \).
\}

\textbf{4. Semantics of the \textsc{dlp} \textsuperscript{T} language}

The semantics of the \textsc{dlp} \textsuperscript{T} language is given
through a suitable “explosion” algorithm.

\textbf{Remark 1} It is worth noting that, as already
briefly mentioned, and more deeply discussed in
Section 5, the “explosion” algorithm is actually a
\textit{pseudo}-algorithm, since it might not terminate in
some cases. Nevertheless, we do prefer to keep the
term \textit{algorithm} also in the following.

It is given a \textsc{dlp} \textsuperscript{T} program \( P \). The aim of the
\textit{Explode} algorithm, introduced next, is to remove
template atoms from \( P \). Each template atom \( t \) is replaced with a standard atom, referring to a
fresh intensional predicate \( p_t \). The subprogram \( d_t \),
defining the predicate \( p_t \), is computed taking into
account of the template definition \textit{Def}(t) associated
to \( t \). Actually, many template atoms may be
grouped and associated to the same subpro-
gram. The concept of atom signature, introduced
next, helps in finding groups of equivalent tem-
plate atoms. The final output of the algorithm is
a \textsc{dlp} program \( P' \). Stable models of the originat-
ing program \( P \) are constructed, \textit{by definition}, from
stable models of \( P' \). Throughout this section, we
will refer to Example 1 as running example. By
little abuse of notation, \( a \in P \) (resp. \( a \in r \)) means
that the atom \( a \) appears in the program \( P \) (the
rule \( r \), respectively).

\textbf{Definition 3} Given a template atom \( t \), the corre-
sponding \textit{template signature} \( s(t) \) is obtained from
\( t \) by replacing each standard term with a conven-
tional (mute variable) ‘\_’ symbol. Let \textit{Def}(s(t))
be the template definition associated to the sig-
nature \( s(t) \); Given a \textsc{dlp} \textsuperscript{T} program \( P \), let \textit{At}(P)
be the set of template atoms occurring in \( P \). Let \textit{Sig}(\textit{At}(P))
be the set of signatures \( \{ s(t) : t \in \textit{At}(P) \} \).

\[ \text{For instance, } \max[p(*,S,$)](M) \text{ and } \max[p(*,a,
$,\_,$)](\_). \]

\textbf{4.1. The Explode algorithm}

The \textit{Explode} algorithm (\( E \) in the following) is
sketched in Figure 4.1. It is given a \textsc{dlp} \textsuperscript{T}program
\( P \) and a set of template definitions \( T \). The output
of \( E \) is a \textsc{dlp} program \( P' \). \( E \) takes advantage
of a stack of signatures \( S \), which contains the set of
signatures to be processed; \( S \) is initially filled up
with each template signature occurring within \( P \).
The purpose of the main loop of \( E \) is to iter-
avely apply the \( \mathcal{U} \) (Unfold) operation to \( P \), until
\( S \) is empty. Given a signature \( s \), the \( \mathcal{U} \) operation
generates from the template definition \textit{Def}(s) a
\textsc{dlp} \textsuperscript{T} program \( P^s \) which defines a fresh predicate \( t^s \),
where \( t \) is the template name of \( s \). Then, \( P^s \) is
appended to \( P \); furthermore, each template atom
\( a \in P \), such that \( a \) has signature \( s \), is replaced
with a suitable atom \( a^s(X') \). It is important point-
The program $P^*$ is constructed.

The program $P^*$ is built in two steps. On the first step, $P^*$ is enriched with a set of rules, intended in order to deal with projection variables.

For each $p_i \in s$, we introduce a predicate $p_i^*$ and we enrich $P^*$ with the auxiliary rule $p_i^*(X'_i) \leftarrow p_i(X'_i)$, where:

- $X'_i$ is built from $X_i$ substituting $pr(X_i)$ with $fr(pr(X_i))$, substituting $pa(X_i)$ with $fr(pa(X_i))$, and substituting $st(X_i)$ with $fr(st(X_i))$.

- $X'_i$ is set to $fr(st(X_i)) \& fr(pa(X_i))$.

For instance, given the signature $s_2 = max[student(\#,\$)](\#)$ and the example template definition given in Example 1, let $L$ be the list $(\#,\$,$\#)$; it is introduced the rule:

$$student^z(F_{st(L)},1,F_{pa(L)},1) : - student(F_{st(L)},1,F_{pr(L)},1,F_{pa(L)},1).$$

Note that projection variables are filtered out from $student^z$. In the second step, for each rule $r$ belonging to $D(s)$, we create an updated version $r'$ to be put in $P^*$, where each atom $a \in r$ is modified this way:

- if $a$ is $f_i(Y)$ where $f_i$ is a formal predicate, it is substituted with the atom $p_i^*(Y')$. $Y'$ is set to $fr(st(X_i)) \& Y$.

- if $a$ is a either a standard (included atoms having $t$ as predicate name) or a special atom (in this latter case a occurs within a template atom) $p(Y)$, it is substituted with an atom $p^*(Y')$, where $Yvec' = fr(st(X_1)) \& \ldots \& fr(st(X_n)) \& Y$.

**Example 9** For instance, consider the rule

$$max(X) \leftarrow p(X), \not exceeded(X),$$

from Example 1, and the signature

$s_2 = max[student(\#,\$,$\#)](\#);$ let $L$ be the special list $(\#,\$,$\#)$; according to the steps introduced above, this rule is translated to

$$max^z(F_{L,1},X) \leftarrow student^z(F_{L,1},X), \not exceeded^z(F_{L,1},X).$$

### 4.3. How template atoms are replaced$^4$

Consider a template atom in the form

$$t[p_1(X_1), \ldots, p_n(X_n)](X_{n+1})$$

It is substituted with

$$t^*(X')$$

where

$$X' = st(X_1) \& \ldots \& st(X_n) \& Y.$$

$^4$Depending on the form of $D(s)$, some template atom might not to be allowed, since some atom with same predicate name but with mismatched arities could be generated.
Example 10 The complete output of $E$ on the constraint

$$\leftarrow \max[\text{student}(\_ \$ \_ \_)](M), M > 25.$$ 

coupled with the template definition of $\max$ given in Example 1 is:

$$\text{student}^2(S_1, P_1) \leftarrow \text{student}(S_1, \_ P_1).$$

$$\text{exceeded}^2(F_{L,1}, X) \leftarrow \text{student}^2(F_{L,1}, X),$$

$$\text{student}^2(F_{L,1}, Y),$$

$$Y > X.$$ 

$$\max^2(F_{L,1}, X) \leftarrow \text{student}^2(F_{L,1}, X),$$

$$\text{not exceeded}^2(F_{L,1}, X).$$

$$\leftarrow \max^2(\text{Sex}, M), M > 25.$$ 

We are now able to give the formal semantics of DLP$^T$. It is important highlighting that stable models of a DLP$^T$ program are, by definition, constructed in terms of stable models of an equivalent DLP program.

Definition 4 Given a DLP$^T$ program $P$, and a set of template definitions $T$, let $P'$ the output of the Explode algorithm on input $(P, T)$. Let $H(P)$ be the Herbrand base of $P'$ restricted to those atoms having predicate name appearing in $P$. Given a stable model $m \in M(P')$, then we define $H(P) \cap m$ as a stable model of $P$.

Note that the Herbrand base of a DLP$^T$ program is defined in terms of the Herbrand base of a DLP program which is not the output of $E$.

5. Theoretical properties of DLP$^T$

The explosion algorithm replaces template atoms from a DLP$^T$ program $P$, producing a DLP program $P'$. It is very important to investigate about two theoretical issues:

- Finding whether and when $E$ terminates; in general, we observe that $E$ might not terminate, for instance, in case of recursive template definitions. Anyway, we prove that it can be decided in polynomial time whether $E$ terminates on a given input.
- Establishing whether DLP$^T$ programs are encoded as efficiently as DLP programs. In particular, we are able to prove that $P'$ is polynomially larger than $P$. Thus DLP$^T$ keeps the same expressive power as DLP. This way, we are guaranteed that DLP$^T$ program encodings are as efficient as plain DLP encodings, since unfolded programs are always reasonably larger with respect to the originating program.

Definition 5 It is given a DLP$^T$ program $P$, and a set of template definitions $T$. The dependency graph $G_{T,P} = (V, E)$ of $T$ and $P$ is a graph encoding dependencies between template atoms and template definitions, and it's built as follows. Each template definition $t \in T$ will be represented by a corresponding node $v_t$ of $V$. $V$ contains a node $v_P$ associated to $P$ as well. $E$ will contain a direct edge $(v_t, v_{v_P})$ if the template $t$ contains a template atom referring to the template $t'$ inside its subprogram (as for the node referred to $P$, we consider the whole program $P$). Let $G_{T,P}(u) \subseteq G_{T,P}$ be the subgraph containing nodes and arcs of $G_{T,P}$ reachable from $u$.

Lemma 1 It is given a DLP$^T$ program $P$, and a set of template definitions $T$. Let $v_P$ the node of $G_{T,P}$ corresponding to $P$. If $G_{T,P}(v_P)$ is acyclic then $E$ terminates whenever applied to $P$ and $T$.

Proof. We assume $G_{T,P}(v_P) = (N, E)$ is acyclic. We can state a partial ordering $\gg$ between its nodes, such that for each $v, v' \in N$, $v \gg v'$ if either $(v, v') \in E$ or there is a $v''$ such that $v \gg v''$ and $v'' \gg v$.

We can build a total ordering $\succ$ by extending $\gg$ in a way that, whenever neither $v \gg v'$ nor $v \gg v'$ holds, it is chosen appropriately whether $v \gg v'$ or $v' \gg v$ holds. This can be done, for instance, by performing an in-depth visit of $G_{T,P}(v_P)$ and taking the resulting order of visit.

Let $\text{level}(v)$ be defined as follows:

- $\text{level}(v) = 0$ if there is no $v'$ such that $v' \gg v$;
- for $i > 0$, $\text{level}(v) = i$ if $i$ is the maximum value such that there is a $v'$ such that $\text{level}(v') = i - 1$ and $v \gg v'$.

Note that $\text{level}(v) > \text{level}(v')$ iff $v \gg v'$.

Given a queue $S$ of signatures, let $\text{level}(S)$ be $\max_{\text{def}(s) \in S} \text{level}(v_{\text{def}(s)})$. 

We will assume $S$ is managed as a priority queue such that an element $s \in S$ having better value of $\text{level}(v_{\text{def}}(s))$ is extracted first\(^4\). Note that $\mathcal{E}$ has a main loop where at each iteration a signature $s$ is popped from $S$, whereas a new set of signatures $S'$ is put in $S$. A new signature $s' \in S'$ can be put on $S$ iff $\text{Def}(s) > \text{Def}(s')$. This means that $\text{level}(S)$ is non-increasing from one iteration to another.

$\text{level}(S)$ can stay unchanged from one iteration $i$ to the next iteration $i + 1$ only if there is some $s'$ such that $\text{Def}(s) = \text{Def}(s')$ still in $S$ at the beginning of iteration $i + 1$. But, in this case, during iteration $i + 1$, the cardinality of the set \{s' s.t. Def(s) = Def(s')\} is decreased by 1, since a new signature referring to the same template definition (and having same level) will be extracted from $S$.

Thus, there exists an iteration $j$, such that the difference $j - i$ has a maximum value bounded by $|\{s' s.t. \text{Def}(s) = \text{Def}(s')\}|$, where $s$ is the signature extracted at iteration $i$.

$\mathcal{E}$ will terminate once $\text{level}(S)$ is 0 and $S$ is emptied up. \hfill \square

**Theorem 2** It is given a DLP\(^T\) program $P$, and a set of template definitions $\mathcal{T}$. It can be decided in polynomial time whether $\mathcal{E}$ terminates when $P$ and $\mathcal{T}$ are taken as input.

**Proof.** We observe that $G_{\mathcal{T}, P}$ can be built in polynomial time. By Lemma 1 we can show that $\mathcal{E}$ terminates if $G_{\mathcal{T}, P}(v_P)$ is acyclic. Vice versa $\mathcal{E}$ does not terminate if we assume there is a cycle in $G_{\mathcal{T}, P}(v_P)$.

In order to show this, assume there is a cycle $C = \{u_0, u_1, \ldots, u_k, u_0\}$, with $k \geq 0$ in $G_{\mathcal{T}, P}(v_P) = (N, E)$.

Since any node of $N$ is reachable from $v_P$, we can assume that $\mathcal{E}$ either loops infinitely or does not terminate until some node $u_l$ such that $(u_l, u_0) \in E$ is reached, i.e., until $\mathcal{E}$ does not enter $C$ or a similar cycle. This means that $\mathcal{E}$ will extract, during some iteration $j$, a signature $s$, such that $\text{Def}(s) = t$, from $S$, and then at least one $s'$ such that $\text{Def}(s') = t_0$ and $s' \in \text{Sig}(\text{At}(P'))$ is added to $S$.

We can prove that starting from the iteration $j$ there is no iteration $j' > j$ such that $S = \emptyset$, and if $\mathcal{E}$ is continued, $\mathcal{E}$ will terminate at the iteration $j'$. \hfill \square

**Definition 6** A set of template definitions $\mathcal{T}$ is said **nonrecursive** if for any DLP\(^T\) program $P$, the subgraph $G_{\mathcal{T}, P}(v_P)$ is acyclic. \hfill \square

It is useful to deal with nonrecursive sets of template definitions, since they may be safely employed with any program. Checking whether a set of template definitions is nonrecursive is quite easy.

**Proposition 1** A set of template definitions $\mathcal{T}$ is nonrecursive if $G_{\mathcal{T}, \emptyset}$ is acyclic.

**Proposition 2** Given a DLP\(^T\) program $P$ and a nonrecursive set of template definitions $\mathcal{T}$, the number of arcs of $G_{\mathcal{T}, P}(v_P)$ is bounded by the overall size of $\mathcal{T}$ and $P$, i.e., it is $O(|\mathcal{T}| + |P|)$.

**Theorem 3** Given a DLP\(^T\) program $P$ and a nonrecursive set of template definitions $\mathcal{T}$, the output $\mathcal{E}$ of $\mathcal{U}$ on input $(P, \mathcal{T})$ is polynomially larger than $P$ and $\mathcal{T}$.

**Proof.** We first observe that each execution of $\mathcal{U}$ adds to $P$ a number of rules (or constraints) whose overall size is clearly bounded by the size of $\mathcal{T}$ (see Figure 4.1). According to Lemma 1, if $\mathcal{T}$ is nonrecursive, the number of $\mathcal{U}$ operations carried out by $\mathcal{E}$ is bounded by the maximum level $l$ (bounded
by the number of nodes of $G_{T,P}(u_P)$, and thus by the size of $T$) which can be assigned to a node of $G_{T,P}(u_P)$, times the number of different template atoms that occur in $P$ and $T$. Thus, the size of $P'$ is $O(|T|^2(|T| + |P|))$. 

In [Dantsin et al., 2001] it’s proved that plain DLP programs (under the brave reasoning semantics) entirely capture the complexity class $\Sigma_2^P$. This bounds the expressive power of $\text{DLP}^T$, too. Indeed, as previously shown, $\text{DLP}^T$ programs may allow to express more succinct encodings of problems, w.r.t. DLP; but, despite this, the expressive power is not increased, accordingly to the following Corollary.

**Corollary 1** $\text{DLP}^T$ has the same expressive power as DLP.

**Proof.** The result is straightforward. Theorem 3 showed as unfolded DLP programs produced as the output of $E$ are polynomially larger than the input programs. In addition, $\text{DLP}^T$ semantics is defined in terms of the equivalent, unfolded, DLP program. Thus, $\text{DLP}^T$ has the same expressiveness properties as DLP. \hfill \Box

### 6. System architecture and usage

The $\text{DLP}^T$ language has been implemented on top of the DLV system [Faber et al., 1999; 2001; Faber and Pfeifer, since 1996]. The current version of the language is available through the DLP-T Web page [Calimeri et al., since 2003]. The overall architecture of the system is shown in Figure 2. The $\text{DLP}^T$ system work-flow can be described as follows.

A $\text{DLP}^T$ program is sent to a $\text{DLP}^T$ pre-parser, which performs syntactic checks (included non-recursivity checks), and builds an internal representation of the $\text{DLP}^T$ program. The $\text{DLP}^T$ Inflater performs the $\text{Explode}$ Algorithm and produces an equivalent DLP program $P'$; $P'$ is piped towards the DLV system. The models $M(P')$ of $P'$, computed by DLV, are then converted in a readable format through the Post-parser module; the Post-parser filters out from $M(P')$ informations about internally generated predicates and rules.

The system introduces also some useful features in order to ease programming. For instance, the possibility to define some predicates as ‘global’, just specifying them in the template definition.

```
#template n0 [f1(b1),...,fn(bn)](b_{n+1})
GLOBAL g1, ..., gm
```

where $g_1, \ldots, g_m$ is a list of predicate symbols defined as global. This introduces the notion of scope. The notion is similar to traditional imperative languages, such as C++, where it is possible to mask global variables. Intuitively, the meaning of the local predicates results from the rules defined within the template body, while the meaning of the global predicates results from the rules belonging to the general program. We refer to function scope in the former case, and program scope in the latter.

**Example 11** In this template definition, node is a global predicate, while coloring is local, and arc is an argument.

```
#template coloring[arc(2)](2) GLOBAL node
{
  coloring(Country, red) v
  coloring(Country, green) v
  coloring(Country, blue) :- node(Country).
  :- arc(Country1, Country2),
      coloring(Country1, CommonColor),
      coloring(Country2, CommonColor).
}
```

### 7. Conclusions

In this paper we have addressed some lacks of DLP, namely code reusability and modularity. We have presented the $\text{DLP}^T$ language, an extension of DLP allowing to define template predicates.

The proposed language is very promising; the future work will have as objectives:

- introducing a clearer model theoretic semantic and prove its equivalence with the current operational semantics;
- generalizing template semantics in order to allow safe and meaningful forms of recursion between template definitions;
- introducing new forms of template atoms in order to improve reusability of the same template definition in different contexts;
- prove the formal equivalence of DLT sub-programs with semantics for aggregate constructs such as in [Calimeri et al., 2005];
- extending the template definition language using standard languages such as C++, such as in [Eiter et al., 2005];
- consider program equivalence results [Eiter et al., 2004] in order to optimize the size of unfolded programs.

The DLP\(^T\) system prototype is available at http://dlp.gibbi.com/
