Muscle strength, aerobic capacity and physical activity in independent

ambulating children with lumbosacral spina bifida

Departments of <sup>1</sup>Paediatric Physiotherapy and Exercise Physiology, and <sup>2</sup>Paediatric Rehabilitation Medicine, Wilhelmina Children's Hospital, University Medical Centre, Utrecht, <sup>3</sup>Rehabilitation Centre 'De Hoogstraat', Utrecht, and <sup>4</sup>Research group of Lifestyle and Health, University of Applied Sciences, The Netherlands

(**4**) Accepted ????

#### Abstract

*Purpose.* This cross-sectional study investigates deficits and associations in muscle strength, 6-minute walking distance (6MWD), aerobic capacity ( $VO_{2peak}$ ), and physical activity (PA) in independent ambulatory children with lumbosacral spina bifida.

*Method.* Twenty-tree children participated (13 boys, 10 girls). Mean age (SD): 10.4 ( $\pm$ 3.1) years. Muscle strength (manual muscle testing and hand-held dynamometry), 6MWD, VO<sub>2peak</sub> (maximal exercise test on a treadmill), and PA (quantity and energy expenditure [EE]), were measured and compared with aged-matched reference values.

*Results.* Strength of upper and lower extremity muscles, and  $VO_{2peak}$  were significantly lower compared to reference values. Mean Z-scores ranged from -1.2 to -2.9 for muscle strength, and from -1.7 to -4.1 for VO2peak. EE ranged from 73-84% of predicted EE. 6MWD was significantly associated with muscle strength of hip abductors and foot dorsal flexors.  $VO_{2peak}$  was significantly associated with strength of hip flexors, hip abductors, knee extensors, foot dorsal flexors, and calf muscles.

*Conclusions.* These children have significantly reduced muscle strength, 6MWD, VO<sub>2peak</sub> and lower levels of PA, compared to reference values. VO<sub>2peak</sub> and 6MWD were significantly associated with muscle strength, especially with hip abductor and ankle muscles. Therefore, even in independent ambulating children training on endurance and muscle strength seems indicated.

Keywords: Spina bifida, child, exercise test, physical fitness, muscle strength, performance

#### Introduction

Over the last decade, few studies have reported on problems in young children with lumbosacral spina bifida (SB) [1-4]. There is increasing evidence that physical fitness in children with SB is impaired, even in those with lumbosacral lesions [2-4]. Several studies on aerobic capacity showed that oxygen cost of walking is significantly higher compared to healthy peers [2,3]. This is partly attributable to their altered gait pattern. Many compensatory movements are observed in the frontal and sagittal plane, particularly caused by muscle weakness in lower extremities [2,4]. There is very weak evidence that exercise training can improve muscle strength and physical fitness in children with SB [5]. At the same time, studies on determinants of physical fitness are scarce. This information is important for designing proper exercise programs to improve physical fitness in children who will benefit most. The purposes of the present study were two-fold. First, we investigated muscle strength, six-minute walking distance (6MWD), aerobic capacity, and physical activity (PA) in two groups of ambulatory children with lumbosacral SB. We compared the outcome of children with myelomeningocele (MMC), who mostly have hydrocephalus and Chiairi II malformation, to

those with lipomyelomeningocele (LMMC), where there is only involvement of the spinal cord. In addition, each group was compared with reference values of the normal population. Second, we investigated associations between muscle strength on the one hand and aerobic parameters and PA on the other.

#### Methods

#### Participants

115

120

125

130

135

140

150

155

170

The study group consisted of 23 children diagnosed with MMC or LMMC, from the SB clinic of the Wilhelmina University Children's Hospital, Utrecht, The Netherlands. Participants included those with paralysis level L5 or below, Intelligence Quotient (IQ) > 80, aged 6–18 years and being able to ambulate 500 m or more without crutches or parawalkers. Participants who had surgery less than six months prior to inclusion, and those with monoparesis or cerebral movement impairments were excluded, as were Non-Dutch speaking participants.

Thirty-three subjects met the inclusion criteria, 23 of them were willing to participate (13 boys and 10 girls). Their general characteristics are presented in Table I. The parents of 10 patients refused to participate. There were no differences in terms of gender, mean age, or ambulation level between the MMC and LMMC group.

All study procedures were approved by the University Medical Ethics Committee. Informed consent was obtained from the parents and the participants themselves when they were  $\geq 12$  years of age.

#### Measurements

All measurements were performed by the same experienced researchers for all participants.

Data concerning the presence of shunted hydrocephalus, mental status (IQ), and lesion level,

| Table I. | Patient | characteristics. |  |

MMC, myelomeningocele; LMMC, lipomyelomeningocele; SD, standard deviation.

according to the ASIA criteria [6], were obtained from the medical records.

Ambulation level was defined according to Hoffer et al. [7]. The scoring was adapted for children with normal ambulatory skills. In Hoffer et al.'s description, participants with normal ambulatory skills are not distinguished from community walkers (walking outdoors with/without braces and possibly using a wheelchair for longer distance). This difference was considered clinically important, and we described participants who did not need a wheelchair at all, as 'normal ambulant' (community ambulator = + Ankle-Foot-Orthosis (AFO), + wheelchair (WC); normal ambulator = +/- AFO, - WC).

#### Anthropometrics

Body weight and height, were measured to calculate Body Mass Index (BMI), and compared with reference values for healthy subjects matched for age and sex. Z-scores were calculated [8]. Body composition was assessed using the sum of seven skin folds according to Pollack et al. [9]. The measurements were taken at the biceps, triceps, supra-iliacal, midabdominal, subscapular, medial thigh, and calf, at the right side of the body.

#### Muscle strength

Muscle strength in upper and lower extremities was graded 0-5 according to the standard Manual Muscle Testing (MMT) as described by Hislop [10]. As intertester reliability of MMT is poor (range in coefficients: 0.11-0.58) [11], all tests were performed by the same examiner. As MMT appears to be less specific for grade  $\geq 4$  [11], in addition for muscles > 4, Hand-Held Dynamometer (HHD) (Citec, type CT 3001, CIT Techniques, Groningen, The Netherlands) was used to quantify isometric maximal muscle strength (in Newton). The tests were performed according to Beenakker et al. [12]. We tested: Shoulder abductors, wrist extensors, hip and knee flexors, hip abductors, hip and knee extensors, ankle dorsal flexors, and grip strength. The plantar flexors were not measured using HHD, as reference values were not available. Muscle strength was compared with Dutch reference values for healthy subjects matched for age and sex, obtained from Beenakker et al. [12]. HHD data were used for studying correlations, with the exception of plantar flexors. In these muscles only MMT data were available.

#### Six-minute walking distance (6MWD)

The 6-minute walking test was performed on an 8meter track in a straight corridor as described 175

180

185

190

195

200

210

215

220

previously [13]. Participants were instructed to cover
the largest possible distance in 6 minutes at a selfchosen walking speed. Encouragements were provided according to the ATS Guideline [14]. 6MWD and average walking speed were measured. 6MWD was compared with reference values of the normal population [13,15].

After the 6-minute walking test, subjects performed a

maximal exercise test using a treadmill (Enmill,

Enraf, Delft, The Netherlands). Between the 6-

minute walking test and the maximal exercise test, there was a recovery period of at least 15 min. After

this period, all participants were able to start walking

without tiredness. It is known from the literature that

children recover significantly faster than adults from

an exercise bout [16]. For both tests, participants

were allowed to use their orthosis or orthopaedic

shoes. In order to accommodate children of varying

abilities, two progressive exercise test protocols were

used. Children, who were community ambulant,

were tested with a starting speed of 2 km/h that was

gradually increased with a speed of 0.25 km/h every

minute. Children who were normal ambulant, were tested with a starting speed of 3 km/hr that was

increased with 0.50 km/h every minute. The proto-

cols were continued until the participant voluntarily

stopped due to exhaustion, despite verbal encour-

agement of the test leader. Maximal walk/run speed

was recorded. During the maximal exercise test,

physiologic responses were measured using a heart

rate (HR) monitor (Polar) and calibrated mobile gas

analysis system (Cortex Metamax B<sup>3</sup>, Cortex Med-

ical GmbH, Leipzig, Germany). The Cortex Metamax is a valid and reliable system for measuring

Peak oxygen uptake (VO<sub>2peak</sub>) was taken as the average value over the last 30 seconds during the

maximal exercise test. Relative VO<sub>2peak</sub> (VO<sub>2peak/kg</sub>)

was calculated as VO<sub>2peak</sub> divided by body mass.

Peak oxygen pulse was calculated as VO<sub>2peak</sub>/HR<sub>peak</sub>. Predicted VO<sub>2peak</sub> values were obtained from estab-

lished values from age- and sex-matched Dutch

A diary was used to estimate daily PA, both the

quantity of activities, and energy expenditure (EE) according to Bouchard [19]. The diary included

static activities (sleeping, lying, or sitting) as well as

dynamic activities (transfers, walking, running,

sporting, etc.). The quantity of PA was determined

by mean daily hours of dynamic activities from the

ventilatory parameters during exercise [17].

reference values [18].

diary.

#### Aerobic capacity

240

245

250

255

260

270

0.7

280

285

The term EE was used for the calculation of MET's according to Bouchard [19]. In the record, every 15-min period over three days, including a Saturday, was qualified in terms of energy costs on a 1 (=sleeping or resting in bed) to 9 scale (=high intensity sport activities or sport competition), corresponding to a range of 1.0 metabolic equivalent transformation (MET) to 7.8 METs and higher [19]. Approximate median energy cost for each of the nine categories in kcal/kg/15 min was used to compute the EE for each individual. The measured total EE was compared with predicted values of healthy peers adjusted for height, sex and age [20].

3

295

305

310

315

320

325

An estimation of daily EE for any of the days of the activity record appears quite reproducible [19]; the intraclass reliability correlations range from 0.86–0.95. Mean Kcal energy expenditure for the three days was highly reliable with a correlation coefficient of 0.96 (p < 0.01). It appears to be a reliable method in children (r=0.91; p < 0.01 [18]) and has been used previously in children with MMC [20].

The diaries were filled out at the end of the day by the participants themselves, assisted by their parents.

#### Statistical analysis

Associations between muscle strength on the one hand, and 6MWD, aerobic parameters and PA on the other, were tested with Pearson's correlations. Alpha level was set at p < 0.05 for all analyses. Ttests were used to test differences between both groups (MMC vs. LMMC) and the normal reference values. If scores were skewed, nonparametric tests Mann-Whitney U-test were used (skin folds measurements, VO<sub>2peak</sub>, grip strength, knee flexor and dorsal flexor strength). Statistical analyses were performed using SPSS for Windows (version 12.0, SPSS Inc, Chicago, Ill, USA).

Results

#### Anthropometrics

Results are shown in Table II. In both groups, body height was significantly lower compared to reference values (MMC p=0.03; LMMC p=0.008). BMI was only significantly higher in MMC group (p=0.03) compared to healthy peers.

#### Muscle strength

We found no significant differences between participants in the MMC vs. LMMC group. Therefore, data are presented for the total group. As can be appreciated from Table III, the MMT indicated that in >25% of participants, muscle strength in the hip abductors and the

375

380

385

395

360

365

370

plantar flexors were <3. Moreover, <50% of the participants had fully functioning hip extensors (grade 5).

Z-scores of muscle strength measured with HHD (Figure 1) were significantly reduced compared to reference values (all P values < 0.01) in lower as well as in upper extremities (mean range: -1.2 to -2.9). Even in the participants without paralysis when measured with MMT (grade 5), strength was significantly reduced in all muscle groups compared to healthy peers (mean range: -1.4 to -3.0).

#### Six-minute walking distance

The mean 6MWD was 353 m (SD  $\pm$  108) in the 390 MMC group, compared to 424 m (SD + 65) in the LMMC group (p = 0.07), and was significantly lower compared to reference values of healthy peers (664 metre SD  $\pm$  65.3; *p* = 0.03).

#### Aerobic capacity

VO<sub>2peak</sub>, VO<sub>2peak/kg</sub> and HR<sub>peak</sub> in children with MMC and LMMC were significantly reduced compared to healthy peers (all p values < 0.05) (Figure 2), but not different between the MMC vs. LMMC group.

Maximal treadmill walk/run speed was significantly lower in the MMC group compared to the LMMC group, 6.3 (SD + 2.1) vs. 8.4 (SD + 1.7)respectively (p = 0.03).

Even in the seven participants without paralysis (4MMC, 3LMMC), aerobic capacity was impaired. Mean Z-score for VO<sub>2peak</sub> was: -2.0 (SD  $\pm$  0.8), Z-score for VO<sub>2peak/kg</sub>: -2.7 (SD  $\pm$  1.4), and their HR<sub>peak</sub> was reduced as well (Z-score -3.5  $[SD \pm 2.3]).$ 

#### Physical activity

There were no significant differences between the LMMC and MMC group in terms of PA. The mean daily hours of dynamic activities was 2.8 for the total group. A total of 57% used an active mode of transportation to school (35% bicycle, 22% walked). All others used an inactive mode of transportation (car or taxi).

Mean EE was significant lower in both groups 455 compared to predicted normal EE; 5953 KJoule/day

420

440

(SD  $\pm$  1626) in the MMC group (p = 0.009) (is 73%  $\pm$  SD 10 of predicted EE), and 7226 KJoule/ day (SD  $\pm$  2260) in the LMMC group (p = 0.03) (is 84%  $\pm$  SD 13% of predicted EE).

## Correlations between muscle strength, 6MWD, aerobic capacity and PA

510 The correlations are presented in Tables IV and V. The 6MWD was significantly associated with muscle strength of hip abductors (0.47, p = 0.04) and foot dorsal flexors (0.55, p = 0.02), whereas peak tread-

500

mill walking/running speed ( $V_{peak}$ ) showed significant associations with the strength of plantar flexor muscles (0.59, p = 0.01).  $VO_{2peak}$  was significantly associated with muscle strength of hip flexors (r = 0.50, p = 0.02), hip abductors (r = 0.51, p = 0.03), knee extensors (r = 0.48, p = 0.03), foot dorsal flexors (r = 0.48, p = 0.048), as well as with calf muscles (r = 0.52, p = 0.049).  $Vo_{2peak/kg}$  was significantly associated with strength of plantar flexor muscles (r = 0.44, p = 0.045). Neither aerobic capacity, nor muscle strength were significantly correlated with PA.

## Discussion

Our study shows that independent ambulating children with SB have significantly reduced muscle strength, 6MWD, aerobic capacity and lower levels of PA, compared to reference values. 6MWD and aerobic capacity were significantly associated with muscle strength, especially with hip abductor and ankle muscles.

In 26% of the participants the strength of hip abductor and calf muscles was below grade 4, resulting in a waddling or crouched gait, that might be energy consuming [3,4]. The reduced muscle strength in the lower extremities is in line with previous research [1,2,4]. Compared to healthy peers, we found significantly reduced strength in all lower extremity muscles, even in MMT grade 5. We observed significantly reduced muscle strength in the upper extremities. It is known that, in children with SB, the loss of muscle function below the actual level of the lesion directly affects motor performance [21]. This may impair daily functioning and influence general activity levels. The strength of intact, functional muscle groups may, according to our

data, is indirectly affected in this population as well. It might be due to deconditioning or to a certain defect in the neural drive of upper extremity muscles.

In all our participants maximal aerobic capacity was impaired, even in participants without paralysis. Since its relationship with muscle strength, aerobic capacity might be related to functional muscle mass of the patient. This has been previously suggested by Agre et al. [22]. They emphasized the importance of HHD measurements and recommended further studies to investigate the role of muscle mass in ambulatory children with SB [22].

Van den Berg-Emons et al. [23] found that adolescents and young adults with MMC (particularly non-ambulatory) were considerably hypoactive when compared to healthy peers. This was also observed in 13 to 20-year-old patients using the doubly-labelled water method [23]. Moreover, levels of objectively measured PA seemed to be significantly related to ambulation level and fitness [23]. In contrast to Van den Berg-Emons et al. [23], we found no significant associations between PA with any of the measured physical fitness parameters. This might be explained by the fact that the ambulation 660

585

685 level and the quantity of PA were homogenous within our participants.

Questions can be raised regarding measurement of  $VO_{2peak}$  and PA (quantity and EE) in this study, as protocols to measure  $VO_{2peak}$  and PA are not available for children with SB. Our results regarding PA (quantity and EE) should be interpreted with caution. Although an estimation of daily EE, from the activity record according to Bouchard et al. [19], appears to be a reliable method in children [19] and has been used previously in children with MMC [20], we might have underestimated the EE as the 'waddling' gait, as well as other PA which might be more energy consuming compared to healthy subjects.

There are no valid and reliable instruments for measuring PA and EE in children with SB, except for the very expensive doubly-labelled water method as previously used [24]. In future studies, accelerometers [25,26] in combination with heart-rate monitoring [27] and indirect calorimetry should be used, to estimate the intensity of daily activities more precisely.

We found aerobic capacity to be strongly related with muscle strength. Nonetheless, PA, quantity as well as EE, showed no correlations with physical fitness parameters. There is weak evidence that exercise training can improve fitness and strength in children with SB [5]. To our knowledge only one study in a heterogeneous group of eight participants exercising for 1 hour/week for 10 weeks showed improvements in muscle strength, exercise capacity, and self-concept [5]. Moreover, a low initial fitness level might provide a 'large room for improvement' for children with a chronic condition. Since there is a lack of clinical evidence, a rigorous designed exercise intervention trial in children with SB seems indicated.

> It is our recommendation that prior to doing future research on improving physical fitness valid and reliable protocols for these children should be developed to measure cardio- respiratory fitness and PA.
