Abstract—Cooperative diversity is a promising technology for future wireless networks. In this paper, we consider a cooperative communication system operating in an amplify-and-forward (AF) mode with an imperfectly-known relay fading channel. It is assumed that a pilot symbol assisted modulation (PSAM) scheme with linear minimum mean square estimator (LMMSE) is used for the channel estimation. A simple and easy-to-evaluate asymptotical upper bound (AUB) of the symbol-error-rate (SER) is derived for uncoded AF cooperative systems with quadrature amplitude modulation (QAM) constellations. Based on the AUB, we propose a criterion for the choice of parameters in the PSAM scheme, i.e., the pilot spacing and the Wiener filter length. We also formulate an optimum power allocation problem for the considered system. The optimum power allocation can be found by means of a gradient search over a continuous range. Numerical simulations are presented to verify the correctness of the theoretical results and the benefits of the parameters optimization.

I. INTRODUCTION

Recently, a new form of spatial diversity named “cooperative diversity” has attracted much research interest because of the fact that it provides effective diversity benefits for those devices that cannot be equipped with multiple antennas due to the size, complexity and cost. Different cooperative protocols have been proposed to exploit the cooperative diversity (see, e.g., [1]–[4], references therein). Among these protocols, one commonly used protocol is the amplify-and-forward (AF) protocol, in which the relay terminal simply re-transmit a scaled version of the received signal to the destination terminal. Depending on the scaling factor, the AF relaying scheme can be further divided into two types which are called fixed gain AF system and variable gain AF system [12].

The performance of AF cooperative systems has been studied in the past from various aspects. For example, [4]–[6] analyzed the performance of AF systems in terms of the outage probability and diversity gain under different assumptions for the amplifier gain. On the other hand, [7]–[11] derived exact expressions of the symbol-error-rate (SER) and various SER bounds for an AF cooperative communication system. However, all these papers have assumed that the perfect channel state information (CSI) is available to both the relay and destination terminal. More recently, [12] and [13] have studied the performance of AF cooperative communication systems with channel estimation error by means of Monte Carlo simulations. The accurate SER expression for cooperative communication systems with a pilot symbol assisted modulation (PSAM) scheme employing a linear minimum mean square estimator (LMMSE) is derived in [14]. To the authors’ best knowledge, no work has been done to deal with issues such as parameters optimization and optimum power allocation for variable gain AF cooperative communication systems with a PSAM scheme.

The difficulty in the optimized design for the considered system is that there are two integrating operations in the accurate SER expression [14]. This prevents us from minimizing the SER directly. In this paper, we propose to use the asymptotic upper bound (AUB) of the SER to overcome these difficulties. In particular, we derive a tight expression for the AUB of the SER for the AF cooperative communication system with a PSAM scheme. The derived AUB has a simple form and no integrating operation is involved. Using the AUB of the SER, we present the criterion for the parameters choice in the PSAM scheme and show that two parameters used in this scheme, i.e., pilot spacing and Wiener filter length, can be chosen in a tradeoff between system performance, pilot overhead, and receiver complexity. With the derived tight AUB, an optimum power allocation problem is also formulated for the AF cooperative communication system. Since the optimization of the power allocation is very complicated as it is related to many terms, and obtaining an analytical solution is unlikely, we propose to find the optimum power allocation by means of a gradient search over a continuous range.

The rest of the paper is organized as follows. In Section II, we describe the system model and some preliminaries of the AF cooperative system with a PSAM scheme. In Section III, we derive an AUB of the SER for an AF cooperative communication system with LMMSE. In Section IV, we first deal with the parameters optimization for the PSAM scheme. Then, an optimum power allocation problem is formulated. A gradient search algorithm is also proposed to find the solution of the optimization problem. Various simulation results and their discussions are presented in Section V. Finally, Section VI contains the conclusions.

The following notation is used throughout the paper: $(\cdot)^*$, $(\cdot)^T$, $(\cdot)^H$, and $(\cdot)^{-1}$ denote the complex conjugate, vector (or matrix) transpose, conjugate transpose, and matrix inverse, respectively. The symbol $\mathbb{E}[\cdot]$ denotes the expectation operator, $|z|$ represents the absolute value of a complex number $z$, and the complex Gaussian distribution with
mean $m$ and covariance $P$ is denoted by $\mathcal{CN}(m, P)$. Finally, $x \sim \mathcal{CN}(m, P)$ denotes a complex random variable $x$ with distribution $\mathcal{CN}(m, P)$.

II. SYSTEM MODEL

We consider an AF-based cooperative communication system which consists of a source, relay, and destination terminal. We assume that each terminal is equipped with a single transmit and receive antenna and operates in a half-duplex mode, i.e., it cannot transmit and receive simultaneously. We adopt the so-called Protocol II proposed by Nabar et al. [5] as the user cooperative protocol. This means that two time slots are used to transmit one data symbol. The source terminal communicates with the relay and destination terminal during the first time slot. In the second time slot, only the relay terminal communicates with the destination terminal. This protocol realizes a maximum degree of broadcasting and exhibits no receive collisions [5].

To simplify the following analysis, we consider a symbol-by-symbol transmission, so that the time slot index 1 and 2 can be dropped. Throughout this paper, we assume that the system operates in a Rayleigh flat fading environment with perfect synchronization, and imperfect channel estimation is assumed at the receiver. As in [12], we use a PSAM scheme for the channel estimation. Pilot symbols are periodically inserted in data symbols with an insertion period of $L$ symbols. Since the design of an optimal channel estimator is very complex, we resort to a suboptimal LMMSE. We further assume that the data information symbols are equally probable from a constellation set composed of quadrature amplitude modulation (QAM) symbols of size $M$, and the pilot symbols are selected from a binary phase-shift keying (BPSK) constellation.

With these assumptions, let us look at the received signals corresponding to the $i$th transmitted symbol. The received signals in the first time slot at the destination terminal and the relay terminal are given by

$$r_{SD}(k) = \sqrt{P_s}h_{SD}(k)x(k) + n_{SD}(k),$$

$$r_{SR}(k) = \sqrt{P_s}h_{SR}(k)x(k) + n_{SR}(k),$$

respectively, where $P_s$ is the average power of the transmitted signal at the source terminal, $h_{SD}(k)$ and $h_{SR}(k)$ are the channel coefficients from the source terminal to the destination terminal and distribution $\mathcal{CN}(0, \sigma_{SD}^2)$ and from the source terminal to the relay terminal with distribution $\mathcal{CN}(0, \sigma_{SR}^2)$, respectively, $x(k)$ is the $k$th transmitted symbol from the source terminal, and $n_{SD}(k)$ and $n_{SR}(k)$ are the additive receiver noises at the destination terminal and the relay terminal, respectively, with the same distribution $\mathcal{CN}(0, N_0)$. Throughout this paper, we assume that $\mathbb{E}[|x(k)|^2] = 1$, i.e., the transmitted symbols have an average energy of 1. According to the Protocol II, the relay terminal will first normalize the received signal by a factor of $\sqrt{\mathbb{E}[|P_{SR}(k)|^2]}$ (to ensure the unity of average energy). Then, the normalized signal will be amplified and forwarded to the destination terminal during the second time slot. Therefore, the received signal at the destination terminal within the second time slot is given by

$$r_{RD}(k) = \frac{\sqrt{P_R}}{\sqrt{P_S|h_{SR}(k)|^2} + N_0}h_{RD}(k)r_{SR}(k) + n_{RD}(k),$$

where $P_R$ is the average power of the transmitted signal at the relay terminal, $h_{RD}(k)$ is the channel coefficient from the relay terminal to the destination terminal with distribution $\mathcal{CN}(0, \sigma_{RD}^2)$, and $n_{RD}(k)$ is the additive receiver noise at the destination terminal with distribution $\mathcal{CN}(0, N_0)$. Using (2), we can rewrite (3) as

$$r_{RD}(k) = \frac{\sqrt{P_R}}{\sqrt{P_S|h_{SR}(k)|^2} + N_0}h_{SR}(k)x(k) + n'_{RD}(k),$$

where

$$n'_{RD}(k) = \frac{\sqrt{P_R}}{\sqrt{P_S|h_{SR}(k)|^2} + N_0}h_{RD}(k)n_{SR}(k) + n_{RD}(k).$$

Assuming that $n_{SR}(k)$ and $n_{RD}(k)$ are independent, it can be shown that the noise term $n'_{RD}(k)$ is a complex Gaussian random variable with distribution $\mathcal{CN}(0, (\frac{\sqrt{P_R}}{\sqrt{P_S|h_{SR}(k)|^2} + N_0} + 1)N_0)$.

Since the PSAM scheme is used for the channel estimation, the packed transmission can be divided into blocks by pilot symbols. In each block, there are $L$ symbols in which the first time slot is assigned to a pilot symbol and the remaining $L-1$ symbols are assigned to data symbols. The channel estimation at each symbol position in a block is obtained using $N_1$ pilot symbols on the left of the symbol position and $N_2$ pilot symbols on the right of the symbol position. Therefore, $N = N_1 + N_2$ pilot symbols are used to estimate the channel coefficient of the desired symbol position.

Let us denote the pilot symbols employed to estimate the channel gain $h_{SD}(k)$ of the desired data symbol $x(k)$ as an $N \times 1$ vector $p_{SD} = [x(k-L(N_1-1)-l), ..., x(k-l), x(k+l), ..., x(k+LN_2-l)]^T$, where $l = 1, 2, ..., L-1$ is the offset of the desired data symbol $x(k)$ to the closest pilot symbol on its left side. Using (1), we obtain the received signal vector $r_{SD}$, corresponding to the transmitted pilot vector $p_{SD}$, at the destination terminal as

$$r_{SD} = \sqrt{P_s} \text{diag}(p_{SD})h_{SD} + n_{SD},$$

where $h_{SD} = [h_{SD}(k-L(N_1-1)-l), ..., h_{SD}(k-l), h_{SD}(k+l), ..., h_{SD}(k+LN_2-l)]^T$ and $n_{SD} = [n_{SD}(k-L(N_1-1)-l), ..., n_{SD}(k-l), n_{SD}(k+l), ..., n_{SD}(k+LN_2-l)]^T$ are the channel coefficient and noise component at the pilot symbols’ position for estimating $h_{SD}(k)$, respectively.

Without loss of generality, we assume that positive unit energy symbols are transmitted as pilot symbols, i.e., $p_{SD}$ is an all-one vector. Then, (6) simplifies to

$$r_{SD} = \sqrt{P_s}h_{SD} + n_{SD}. $$

(7)
\[
\mathbf{C}_{SD} = \begin{bmatrix}
P_S R_{SD}(0) + N_0 & P_S R_{SD}(L) & \cdots & P_S R_{SD}((N-1)L) \\
P_S R_{SD}(L) & P_S R_{SD}(0) + N_0 & \cdots & P_S R_{SD}((N-2)L) \\
\vdots & \vdots & \ddots & \vdots \\
P_S R_{SD}((N-1)L) & P_S R_{SD}((N-2)L) & \cdots & P_S R_{SD}(0) + N_0
\end{bmatrix}
\] (8)

\[
e_{SD}(l) = \sqrt{P_S R_{SD}(-L(N_1 - 1) - l)}, \ldots, \sqrt{P_S R_{SD}(L - l)}, \ldots, \sqrt{P_S R_{SD}(L(N_2 - 1) - l)}
\] (9)

With these observations, the channel estimate for \(h_{SD}(k)\) can be obtained by the LMMSE as [15]

\[
\hat{h}_{SD}(k) = \mathbf{w}_{SD} r_{SD},
\] (10)

where \(\mathbf{w}_{SD} = \mathbf{c}_{h_{SD,SD}}(l) \mathbf{C}_{SD}^{-1}\) is an \(1 \times N\) LMMSE filter vector, \(\mathbf{C}_{SD} = \mathbb{E}[r_{SD} r_{SD}^{H}]\) and \(\mathbf{c}_{h_{SD,SD}}(l) = \mathbb{E}[h_{SD}(k) r_{SD}]\) are the autocorrelation matrix of \(r_{SD}\) and cross-correlation vector of \(h_{SD}(k)\) and \(r_{SD}\), respectively. From the LMMSE theory [15], we know that \(\hat{h}_{SD}(k)\) is distributed as \(\mathcal{CN}(0, \mathbf{c}_{h_{SD,SD}}(l) \mathbf{C}_{SD}^{-1} H_{h_{SD,SD}}(l))\). Let us define the discrete autocorrelation function of \(h_{SD}(k)\) as \(R_{SD}(k) = \mathbb{E}[h_{SD}(k) h_{SD}(k + \kappa)]\). Then, using the system model and channel properties described above, we finally obtain \(\mathbf{C}_{SD}\) and \(\mathbf{c}_{h_{SD,SD}}(l)\) as shown at the top of this page. From the LMMSE filter vector \(\mathbf{w}_{SD}\), we can see that each data symbol position in a block requires a different estimator. However, due to the periodic pilot insertion, an identical estimator will be adopted at the same data symbol positions across all blocks in a packet. Therefore, without loss of generality, we will only consider \(L - 1\) different estimators for the data symbol positions in one particular block in the following analysis and employ the index \(l\) instead of \(k\) to distinguish them. With this in mind, we can express the estimation error of the \(l\)th estimator as

\[
e_{SD}(l) = h_{SD}(l) - \hat{h}_{SD}(l).
\] (11)

Furthermore, the estimation error \(e_{SD}(l)\) is distributed as \(\mathcal{CN}(0, \sigma_{e_{SD}}^2(l))\), where \(\sigma_{e_{SD}}^2(l) = \sigma_{SD}^2 - \mathbf{c}_{h_{SD,SD}}(l) \mathbf{C}_{SD}^{-1} \mathbf{c}_{h_{SD,SD}}(l)^{H}\). From (11) it follows that we can model the channel gain \(h_{SD}(l)\) as the sum of the channel estimate \(\hat{h}_{SD}(l)\) and the estimation error \(e_{SD}(l)\), i.e.,

\[
h_{SD}(l) = \hat{h}_{SD}(l) + e_{SD}(l).
\] (12)

Similarly, we can model the channel gain from the source terminal to the relay terminal \(h_{SR}(l)\) and the channel gain from the relay terminal to the source terminal \(h_{RD}(l)\) as

\[
h_{SR}(l) = \hat{h}_{SR}(l) + e_{SR}(l),
\] (13)

\[
h_{RD}(l) = \hat{h}_{RD}(l) + e_{RD}(l),
\] (14)

where \(\hat{h}_{SR}(l), e_{SR}(l), \hat{h}_{RD}(l),\) and \(e_{RD}(l)\) can be attained using the same procedure as above.

III. AUB ANALYSIS FOR AF COOPERATIVE SYSTEMS

With the above assumption and the estimated channel gains, maximum ratio combining (MRC) [16] can be applied at the destination terminal to minimize the SER of the system. Define \(B = 1 - 1/\sqrt{M}\) and \(K_Q = 3/(M - 1)\). The accurate SER expression for the considered system with \(M\)-QAM is [14]

\[
\mathbb{P} = \frac{1}{L - 1} \sum_{l=1}^{L-1} P(l),
\] (15)

where

\[
\begin{align*}
P(l) &= \frac{1}{\pi} \int_{-\pi/2}^{\pi/2} \int_{0}^{1} \frac{4B\eta(l)}{\alpha_1(l) + \frac{K_Q}{2\sin^2 \theta}} f(l, x, \frac{K_Q}{2\sin^2 \theta}) \, dx \, d\theta \\
&- \frac{1}{\pi} \int_{-\pi/4}^{\pi/4} \int_{0}^{1} \frac{4B^2\eta(l)}{\alpha_1(l) + \frac{K_Q}{2\sin^2 \theta}} f(l, x, \frac{K_Q}{2\sin^2 \theta}) \, dx \, d\theta, \\
f(l, x, s) &= \exp \left( -\frac{\alpha_3(l) \beta(l)}{1 - x} \right) \left[ a(l, x, s) + b(l, x, s) \right], \\
a(l, x, s) &= \frac{\alpha_2(l) + (s - 2\alpha_2(l) + \alpha_3(l))x + v(l, x, s)}{\alpha_2(l) + s - \alpha_2(l) + \alpha_3(l)x - sx^2}, \\
v(l, x, s) &= \frac{(\alpha_2(l) + s - \alpha_2(l) + \alpha_3(l)x - sx^2)^2}{\alpha_2(l) + s - \alpha_2(l) + \alpha_3(l)x - sx^2}, \\
\eta(l) &= \alpha_1(l)\alpha_2(l)\alpha_3(l)\exp(\alpha_3(l)\beta(l)), \\
\alpha_1(l) &= \frac{P_S \sigma_{e_{SD}}^2(l) + N_0}{P_S \sigma_{h_{SD}}^2(l)}, \\
\alpha_2(l) &= \frac{(P_R + N_0)\sigma_{e_{RD}}^2(l) + N_0}{P_R \sigma_{h_{RD}}^2(l)}, \\
\alpha_3(l) &= \frac{P_S \sigma_{e_{SR}}^2(l) + N_0}{P_S \sigma_{h_{SR}}^2(l)}, \\
\beta(l) &= \frac{P_S P_R \sigma_{e_{SD}}^2(l) \sigma_{e_{RD}}^2(l) + (1 + \sigma_{e_{RD}}^2(l))N_0^2}{P_S \sigma_{e_{SD}}^2(l) + N_0}(P_R + N_0)(P_R + N_0)^2}
\end{align*}
\]

Note that although the above expression of the SER is easy for numerical evaluation, it is not insightful in terms of its dependence on the system parameters like the pilot spacing or power allocation between the source terminal and relay terminal. To optimize the system parameters using (15) seems to be intractable. Therefore, a simple and insightful AUB of the SER is of special interest.
As derived in [14], we know that the instantaneous SNR of the output signal from the MRC detector is the sum of two terms: the first term is determined by the direct signal from the source terminal and the second term is determined by the relay signal from the relay terminal. Using the result in [14], the instantaneous SNR determined by the relay signal can be rewritten as
\[
\gamma_2(l) = \frac{x_2(l)x_2(l)}{x_1(l) + x_2(l) + \beta(l)}, \quad (16)
\]
where
\[
x_1(l) = \frac{\hat{h}_{RD}(l)\beta}{\sigma_2(l)\sigma_{h,RD}^2(l)},
\]
\[
x_2(l) = \frac{\hat{h}_{SR}(l)\beta}{\sigma_3(l)\sigma_{h,SR}^2(l)}.
\]

From the definition of \(\beta(l)\) in (15), it can be found that \(\beta(l) > 0\). Therefore, if we set \(\beta(l) = 0\) in (16), we get an upper bound of the \(\gamma_2(l)\). With this observation, we obtain an upper bound of SER by simply setting \(\beta(l) = 0\) in (15). After some manipulations, we obtain the AUB of the SER
\[
T_{UB} = \frac{1}{L-1} \sum_{i=1}^{L-1} \frac{4B}{KQ} \alpha_1(l) [\alpha_2(l) + \alpha_3(l)]. \quad (17)
\]
Note that \(N_0/P_R\) tends to zero at high SNR regions. Therefore, the AUB of SER can be further simplified as
\[
T_{UB} = \frac{1}{L-1} \sum_{i=1}^{L-1} \frac{4B}{KQ} \alpha_1(l) [\alpha_2'(l) + \alpha_3(l)], \quad (18)
\]
where
\[
\alpha_2'(l) = \frac{P_R\sigma_{2,RD}^2(l)}{\sigma_{h,RD}^2} + \frac{N_0}{P_R} \approx \alpha_2(l).
\]
As shown in Section V, the AUB of the SER in (18) is very close to the exact SER, especially at high SNR regions.

IV. PARAMETERS OPTIMIZATION

As can be seen from (18), the AUB of the SER is determined by the function
\[
M(L, N, P_S, P_R) = \sum_{i=1}^{L-1} \alpha_1(l) [\alpha_2'(l) + \alpha_3(l)]. \quad (19)
\]
It should be pointed out that \(\alpha_1(l), \alpha_2'(l), \alpha_3(l)\), for \(l = 1, 2, \cdots, L - 1\) are related to the parameters \(L, N, P_S,\) and \(P_R\). This can be deduced from their definition in (15). As a result, we establish the relation between the AUB of the SER and the parameters which need to be optimized. Using the above metric as an optimality criterion, we can now study the parameters optimization problem of the considered system. In principle, we should optimize four parameters \(L, N, P_S,\) and \(P_R\) jointly to get the optimum system performance. However, the joint optimization problem is difficult to solve due to the form of the metric in (19). Therefore, we propose to optimize the parameters of the PSAM and the power allocation separately as shown below. Although this method is suboptimal, our simulation results show that this method provides a satisfactory performance.

A. PSAM Parameters Optimization

For the PSAM scheme, there exists a tradeoff between the system performance, pilot overhead, and receiver complexity. While a smaller pilot spacing \(L\) leads to a better channel estimation, the overhead imposed by the pilot symbols reduces the effective SNR and transmission efficiency. A similar conflict also exists for the choice of the Wiener filter length \(N\). Larger \(N\) is expected from the point of view of accurate channel estimation, but this will increase the receiver complexity. Therefore, the parameters \(L\) and \(N\) should be accordingly chosen by taking all these factors into account. We will use the metric in (19) as the optimality criterion for determining appropriate values of \(L\) and \(N\). In particular, we will set \(P_S = P_R = P/2\), where \(P\) is the total transmitted power, and try to minimize the metric \(M(L, N, P_S, P_R)\) which characterizes (asymptotically) the performance of the considered system. Since there is no closed-form solution to this minimization problem, the suitable values of \(L\) and \(N\) can only be obtained by examining the surf of \(M(L, N, P_S, P_R)\), which is presented in the next section.

B. Power Allocation Optimization

Now, we will study the power allocation problem for the considered system. We assume that the parameters \(L, N\) are fixed and the total transmitted power is \(P = P_S + P_R\). Under these constraints, we are going to optimize \(P_S\) and \(P_R\) so that the SER performance of the system is minimized. Since the metric \(M(L, N, P_S, P_R)\) characterizes (asymptotically) the SER performance of the considered system, we can state the power allocation problem as follows.

Problem Statement: Given positive integers \(L, N\), find a pair of real numbers \(P_S\) and \(P_R\) such that the metric function \(M(L, N, P_S, P_R)\) is minimized under the power constraint of the transmitted power which is fixed to \(P\), i.e.,
\[
\{P_S, P_R\} = \arg \min_{P_S, P_R} M(L, N, P_S, P_R). \quad (20)
\]
Note that the derivatives of the metric \(M(L, N, P_S, P_R)\) with respect to \(P_S\) and \(P_R\) will be expressed as the sum of several high-order polynomials. This prevents us from finding a closed-form solution for \(P_S\) and \(P_R\). Therefore, we propose to find the optimum power allocation by means of a gradient search over a continuous range.

V. NUMERICAL RESULTS

In this section, we will first verify the correctness of the derived expression for the AUB of the SER by simulations. We will then present some illustrative examples for the parameters optimization. We consider an AF cooperative communication system with 4-QAM modulation formats using the PSAM scheme for the channel estimation. Unless stated otherwise,
the following parameters are used in the numerical work. We set \( P_S = P_R \) and assume that the variance of the noise was chosen to be \( N_0 = 1 \). We also assume that the complex channel gains are described by the autocorrelation functions 
\[
R_{SD}(\kappa) = R_{SR}(\kappa) = R_{RD}(\kappa) = J_0(2\pi f_{\text{max}}\kappa T_s),
\]
where \( J_0(x) \) is the zeroth order Bessel function of the first kind, \( f_{\text{max}} \) is the maximum Doppler frequency, and \( T_s \) is the symbol duration. Note that the variances of the complex channel gains are normalized to unity. We further assume that a pilot spacing of \( L = 6 \) is used in the PSAM scheme and the LMMSE with \( N = 6 \) is used for the channel estimation. Note that the power loss resulting from the pilots is accounted for all curves.

Figure 1 shows the theoretical AUB and the Monte Carlo simulation results of the SER for the AF cooperative communication system with 4-QAM. The results are presented for two different levels of the normalized maximum Doppler frequency, i.e., \( f_{\text{max}}T_s = 0.01 \) and \( f_{\text{max}}T_s = 0.05 \). From Fig. 1, we observe that the AUB fits very well with the simulated SER for both cases at high SNR regions.

Assuming \( P_S = P_R \), Figure 2 plots the metric \( M(L, N, P_S, P_R) \) as a function of the pilot spacing \( L \) and the Wiener filter length \( N \) at SNR = 20 dB with a normalized maximum Doppler frequency of \( f_{\text{max}}T_s = 0.05 \). We observe that for a given \( N \), the metric \( M(L, N, P_S, P_R) \) decreases rapidly with \( L \) for \( L \leq 4 \). This is because the energy spent by pilot symbols decreases rapidly with \( L \) for \( L \leq 4 \). As a result, the energy assigned to each data symbol increases, and this leads to a fast decrease in the SER. On the other hand, we also find that the metric \( M(L, N, P_S, P_R) \) increases with \( L \) for \( L > 7 \). This is easy to understand since large \( L \) will increase the channel estimation error, and thus increase the SER. By taking all these factors into account, we suggest to choose \( L = 6 \). Now let us consider the choice of \( N \). From Fig. 2, we observe that for a given \( L \), the metric \( M(L, N, P_S, P_R) \) decreases rapidly with \( N \) for \( N \leq 6 \). However, the decrease in \( M(L, N, P_S, P_R) \) obtained by increasing \( N \) beyond 6 is minor. Since large \( N \) leads to a high receiver complexity, we suggest to choose \( N = 6 \) for this particular case.

Now, we turn our attention to the power allocation strategies. As discussed earlier, we use a constrained gradient-search algorithm to find the power tradeoff between the source terminal and the relay terminal. For example, in case of \( \sigma_{SD,2} = \sigma_{SR,2} = \sigma_{RD,2} = 1 \) and \( f_{\text{max}}T_s = 0.01 \), we find the optimum power allocation is \( P_S/P = 0.66 \), and \( P_R/P = 0.34 \). The performance comparison of the equal power scheme and the optimum power allocation scheme is presented in Figure 3. This figure illustrates that the performance of the system with optimum power allocation is better than that of the system with equal power allocation. We can see a greater performance improvement from the optimum power allocation if the ratio \( \sigma_{RD,2}/\sigma_{RD,2} \) decreases. For example, in case of \( \sigma_{SD,2} = \sigma_{SR,2} = 1 \), \( \sigma_{RD,2} = 10 \) and \( f_{\text{max}}T_s = 0.01 \), we find the optimum power allocation is \( P_S/P = 0.83 \), and \( P_R/P = 0.17 \). The corresponding performance comparison is plotted in Figure 4. As can be seen from the figure, the optimum power allocation scheme has an improvement of 1.5 dB over the equal power scheme. This further demonstrates the effectiveness of the power allocation optimization.

VI. CONCLUSIONS

We dealt with the problem of parameters optimization of AF cooperative communication systems with a PSAM-based LMMSE scheme used for the channel estimation. A tight
and easy-to-evaluate AUB of the SER was derived for the considered system with QAM constellations. Using the derived AUB, we proposed a criterion for the choice of parameters in the PSAM scheme, i.e., pilot spacing and Wiener filter length. We also formulated an optimum power allocation problem for the considered system. The optimum power allocation was found by means of a gradient search over a continuous range. Some illustrative examples for the parameter optimization were presented. The benefits of parameters optimization were demonstrated by the numerical results.
