Abstract

This paper explores hardware-implemented error-detection and security mechanisms embedded as modules in a hardware-level framework called the Reliability and Security Engine (RSE), which is implemented as an integral part of a modern microprocessor. The RSE interacts with the processor through an input/output interface. The CHECK instruction, a special extension of the instruction set architecture of the processor is the interface of the application with the RSE. The detection mechanisms described here in detail are: (1) the Memory Layout Randomization (MLR) Module, which randomizes the memory layout of a process in order to foil attackers who assume a fixed system layout, thus protecting against many security threats, (2) the Data Dependency Tracking (DDT) Module, which tracks the dependencies among threads of a process and maintains checkpoints of shared memory pages in order to rollback the threads when an offending (potentially malicious) thread is terminated, (3) the Instruction Checker Module (ICM), which checks an instruction for its validity or the control-flow of the program just as the instruction enters the pipeline for execution, and (4) Adaptive Heartbeat Monitor (AHBM), which enables heart-beating for checking the liveness of operating systems and/or application processes/threads. Performance simulations for the studied modules indicate low overhead of the proposed solutions.

1 Introduction

There has been significant research in providing hardware mechanisms for reliability, security and recovery. A variety of specific processor-level mechanisms have been proposed for error detection and recovery (e.g., duplication, instruction-retry, control-flow checking, cache-based recovery) on one hand, and security protection (e.g., preventing buffer-overflow, tamper-resistant hardware) on the other. Each technique is based on custom augmentation of the processor; additionally most methods do not provide application specific support. Processor-based mechanisms are important since, from a security perspective they can be less susceptible to attacks and, from the reliability perspective can minimize error propagation and hence enable robust recovery. Application-aware error detection performed with hardware is known to minimize fault propagation, and many security mechanisms need to be application-aware.

A common processor-level framework that can provide application-aware reliability and security is attractive and timely. This paper demonstrates a common framework to provide a variety of application-aware techniques for error-detection, masking of security vulnerabilities and recovery under one umbrella, in a uniform, low overhead
manner. To illustrate our approach, we describe hardware-implemented error-detection and security mechanisms embedded as modules in the hardware-level framework, called the Reliability and Security Engine (RSE), which is implemented as an integral part of a superscalar microprocessor.

The framework serves two purposes: (i) it hosts hardware modules that provide reliability and security services, and (ii) it implements an input/output interface between the modules and the main pipeline and between the modules and the executing software (operating system and application).

Security is provided by the Memory Layout Randomization (MLR) module, which randomly relocates key memory regions (e.g., the start address of the application stack) in a process’ address space to break the fixed memory layout assumed by an attacker and thus defeat a large class of security attacks (about 60% of attacks reported by CERT [1]). Recovery is supported by the Data Dependency Tracking (DDT) module, which tracks the runtime data dependency among threads in a multithreaded process and uses this information to recover a multithreaded application from a thread crash due to malicious (security attacks) faults. Reliability is achieved by introducing: (1) the Instruction Checker Module (ICM), which checks instruction validity or the control-flow of the program as the instruction enters the pipeline for execution, providing coverage for the multiple bit errors in instruction while it is being transferred from memory to the dispatch stage of the pipeline, and (2) Adaptive Heartbeat Monitor (AHBM), which enables heart-beating for checking the liveness of operating system and/or application processes/threads. The operating system and/or application are aware of these mechanisms and can be instrumented using compiler support, to insert a special CHECK for invoking the modules. The instruction set architecture of the core processor is extended to include and support these CHECK instructions.

Earlier work focused on providing software-based solutions [10][11][12][29][30], hardware solutions specific to a particular method of checking [14][15], or fault-tolerance for the hardware rather than directly to the application [16][28]. In contrast, this paper explores a hardware framework that is on-chip and embeds error-detection and security modules to support the application.

2 Related Work

Hardware-implemented error-detection mechanisms are proposed to support control-flow checking by means of watchdogs [14] or embedded signature monitoring for checking data-access faults [15]. Other hardware-based techniques (1) use duplication, as in G4[25] and G5[26], or hardware redundancy, as in DIVA [28], or (2) use existing spare hardware to re-execute the instruction and compare the results [16]-[21].

Most previous work on processor-level security focuses on providing tamper-resistance and cryptography. For example, the IBM 4758 Secure Coprocessor [8] provides both physical tamper-resistance and hardware support for encryption algorithms. Independently, [29] and [31] propose to enhance the existing processor pipeline to detect stack-based buffer overflow attacks.
Cache-based error recovery algorithms in single- or multi-processor systems [34][35] are usually implemented by modifying the cache replacement or cache coherence protocol in order to save copies of dirty cache lines when they have to be replaced. In these algorithms, checkpoints are saved at cache-line granularity. ReVive [32] changes the memory directory controller in shared-memory multiprocessor machines to support rollback recovery. In ReVive, internode memory communication is intercepted at the memory directory controller to achieve memory-based checkpointing, logging, and distributed parity maintenance. This is implemented without processor or cache modification.

Expansions to the pipelines of microprocessors have also been proposed to perform concurrent error checking. Wilken and Kong [15] propose a hardware technique meant specifically for control-flow checking using embedded signature-monitoring for a RISC architecture. The signature monitor is on-chip and executes in parallel with the pipeline. It performs exception handling by saving and restoring the signatures by means of special instructions. The signature monitor generates the signature using opcode and operands of the instruction from the pipeline.

In our approach, the framework incorporates all the inputs of the pipeline and facilitates the embedding of different checking mechanisms for the application. For example, the generic interface can support an instruction checker module that checks the instructions for their validity, a heartbeat monitor module, which receives heartbeats from processes and monitors their execution, and a data dependency tracker module that tracks thread dependencies to minimize the impact of a thread crash on the process execution. The reliability and security engine is a versatile framework, capable of incorporating a variety of reliability, as well as security checking routines. Due to the lack of space, only a few of the modules designed to be embedded in the framework are described in this paper.

3 RSE Framework
The Reliability and Security Engine (RSE) is implemented as an integral part of the processor, residing on the same die. Hardware modules providing error-detection and security services are embedded in the RSE and execute in parallel with the core pipeline. Special CHECK instructions, inserted into a target application by a compiler, provide the interface between the RSE and the application. As instructions are fetched from the pipeline, the CHECK instructions are forwarded to the RSE to invoke the security and reliability hardware checker modules.

A module in the RSE can operate in one of two modes: synchronous and asynchronous. In synchronous mode, the pipeline can commit only when the check executed by the module completes; this mode is used when error-detection is performed concurrent with instruction execution. In asynchronous mode, the pipeline commits an instruction and sends a signal to the RSE. On receiving this signal, the RSE module collects permanent state used for checking and recovery; this mode is used when the module performs operations such as dependency tracking.
and checkpointing, while minimally interfering with the pipeline. Together, the two modes cover a broad range of security and reliability checks.

For example, the Instruction Checker Module (ICM) checks for errors in the binary of an instruction that enters the pipeline and operates in synchronous mode, i.e., the instruction should not be committed until checking in the module is complete. On the other hand, the Data Dependency Tracker (DDT) module, which logs dependency between the threads, operates in asynchronous mode. The dependency produced by an instruction is logged only when the instruction is committed in the pipeline so as not to keep speculative information in the module.

Figure 1 depicts the RSE framework in the context of a superscalar processor (similar to the DLX processor described in [36]) simulated using an augmented *sim-outorder* SimpleScalar\(^1\) [4] simulator. The left side of Figure 1 shows the details of a DLX-like superscalar pipeline structure together with the architectural parameters used in the simulation\(^2\). The RSE framework is shown on the right side (shaded rectangle). The RSE can be broadly divided into two parts: the *input interface* and the *internal hardware modules* that perform the reliability and security checking.

### 3.1 Input Interface of the Framework

The modules in the RSE interface with the execution pipeline through the common input interface. This interface consists of a set of input queues, each of which contains the outputs of a particular pipeline stage. As discussed, additional fan-outs from the pipeline stage outputs of the core processor provide input to the framework. The set of RSE input queues includes:

- \textit{Fetch\_Out} delivers the currently fetched instructions.
- \textit{Regfile\_Data} delivers the operands of an instruction.
- \textit{Execute\_Out} delivers results of ALU operations or address generation.
- \textit{Memory\_Out} provides data values loaded by the pipeline from memory during the current cycle.
- \textit{Commit\_Out} indicates the instructions that are committed or squashed by the pipeline; used to remove the data corresponding to these instructions from the input queues.

Two additional inputs, \textit{Mem} and \textit{Mem\_Rdy}, are used by the MAU (Memory Access Unit in the RSE) to access memory in response to requests from the hardware modules.\(^3\) The number of entries in each input queue is equal to the number of entries in the re-order buffer in the pipeline. For the sake of clarity, Figure 1 only shows the register and the multiplexer (MUX) driving its input for a single entry (the \(i^{\text{th}}\) one) in a queue. The signal wires going across the boundary of the framework and the pipeline are shown as dashed lines. These wires serve two pur-

\(^1\) The SimpleScalar simulator tool set implements an instruction set architecture very similar to MIPS.

\(^2\) We use an L2 Cache size of 128 KB in our simulation. The typical size of L2 Cache in modern microprocessors is 512 KB [37].

\(^3\) These inputs are different from the Memory\_Out input, which receives the output of the memory stage of the pipeline (data loaded by the processor from memory).
poses: (1) to provide data to the input queues on the framework, and (2) to indicate to the pipeline that the instructions can be committed.

**Figure 1: Organization of the RSE Framework (in the context of the simulated superscalar processor derived from the SuperScalar DLX [36] processor)**

The output of a pipeline stage is obtained from one of several possible circuit nodes. For example, the Execute\textsubscript{Out} input queue stores the output produced by the execute stage for an instruction. This includes the outputs of i) the ALU, ii) the MDU (multiply/divide unit), and iii) the LSU (load/store effective address computation unit). These outputs constitute the data inputs to the MUX\textsubscript{3}. The three select inputs to the MUX are IssueALU, IssueMDU, IssueLSU, which, when set, indicate whether the instruction was issued to the ALU, MDU, or the LSU, respectively. Based on these select signals, the appropriate inputs of the MUX are selected to be stored in the input queue entry.

The modules are connected to the appropriate input queues to obtain necessary data, e.g., the MLR module is connected to the Fetch\textsubscript{Out} and the Commit\textsubscript{Out} queues, as shown in Figure 1. Assuming a 32-bit processor with
a re-order buffer size of 16 entries, an estimate of the hardware overhead due to the input queues and input MUXes is approximately 2560 flip-flops and 12,800 gates\(^4\). The delays due to the framework are discussed in Table 3. Clearly, there will be additional delays due to the increased wiring placement and routing, which need to be addressed via efficient circuit design techniques.

Thus, the framework receives predefined inputs from the system, obtained either by providing extra ports to the register file or by introducing additional fan-outs to the pipeline outputs. The resulting delay and overhead is discussed in Table 3. One approach to enabling multiple concurrent accesses to the register file is to use a banked multiported register file.

The interface can handle speculative execution by the pipeline. When the pipeline is flushed in case of a misprediction or misspeculation, the instructions being squashed are passed to the RSE through the Commit\(_{Out}\) input. The RSE uses this information to flush the input queues and the instruction output queue to reflect these changes. As will be seen, no speculative state is maintained in the RSE modules.

**An illustration of instruction execution.** This section presents two example scenarios illustrating the execution of the instructions in the pipeline and the RSE framework. Figure 2(a) shows the execution of instructions in the synchronous case. The “CHK INST_CHECK” in the instruction stream notifies the instruction checker module in the framework that the following instruction ‘beq Label X’ is to be checked. The module fetches a redundant copy of the instruction, compares the two copies and writes the results of the instruction to the pipeline. If no error has been detected by the module, the pipeline commits the instruction. Figure 2 (b) depicts the instruction execution in the asynchronous mode. In this case the “ld C” instruction is encountered by the data dependency tracker module in the framework, and using the effective address calculated by the pipeline, the module tracks whether this read operation makes the current thread dependent upon another thread (details of the algorithm are explained in Section 4.2.1). When the pipeline commits the instruction and sends a signal to the RSE, the module logs the collected dependency information as permanent state.

![Figure 2: Instruction Execution Scenario (a) synchronous mode; (b) asynchronous mode](image)

\[\text{#flip flops for input queues} = (\text{#input queues} \times \text{#entries per input queue} \times \text{#bits per input queue entry}) = (5 \times 16 \times 32) = 2560. \text{ Gate count for individual MUXes with feedback loop (i) 2to1 MUX = 4, (ii) 3to1 MUX = 5 (iii) 4to1 MUX = 6; 2 inputs need 4to1 MUXes, 2 need 2to1 MUXes and 1 input needs a 3to1MUX. Therefore, the total number of gates} = (2 \times 6 + 2 \times 4 + 1 \times 5) \times 32 \times 16 = 25 \times 32 \times 16 = 12800. \text{ (32-bits per input queue entry, 16 entries per input queue).}\]
3.2 Internal Organization of RSE

Figure 1 also shows the internal organization of the RSE (rectangle shaded dark gray). It is divided into three main parts: (1) the memory access unit, which handles the memory access requests for the modules, (2) the instruction output queue used by the modules to communicate results back to the pipeline, and (3) the hardware modules, which implement application-aware error-detection and security mechanisms.

**Memory Access Unit (MAU).** Some checks, e.g., control flow checking, necessitate that the module make an independent memory request. This hardware unit provides memory access for RSE modules and thus eliminates the need for a bus interface unit in each module, which would incur a high overhead. A module places a memory access request consisting of a memory address, the type of access to be made (load/store), the number of bytes to be loaded from or to be stored at that address, and a pointer to a buffer in the module where the data is to be stored/loaded. Clearly, not all modules need memory access; hence not all will use this unit.

An access request is placed in a memory request queue and serviced by the MAU in a cyclic order. The MAU shares the bus interface unit with the main processor pipeline (Figure 1). The requests from the MAU and the main pipeline are arbitrated upon, giving the main pipeline the higher priority. This requires a small modification to the arbitration logic (Arbiter in Figure 1) for bus access to include the MAU as an additional driver. The frequency of memory accesses by the processor is generally low due to high hit rates for the on-chip level 1 and level 2 caches. Thus, even though the arbitration logic incurs a performance overhead whenever the processor accesses memory, the overall impact on the processor’s performance, as shown in Section 5.2, is small. It is clearly less than in the case where the access is performed through the processor cache. Additionally, via this technique, the memory accesses from the framework do not pollute the cache with data that is irrelevant to the application execution in the pipeline.

**Instruction Output Queue (IOQ).** An entry in the instruction output queue is allocated for each instruction (including the CHECK instructions) at the time the instruction is forwarded to the Fetch-Out queue in the framework. This happens simultaneously with the instruction being dispatched in the pipeline. The queue contains the following fields for each entry: (i) check holds the result from the check performed by a module, and (ii) checkValid is used by the main pipeline to determine whether the data in the check field is valid. Together, these two fields constitute the check bits of the IOQ. Interpretation of the check and checkValid bits is described in Table 1.

For a CHECK instruction, these bits (checkValid and check) are initially set to ‘00’. For all other instructions, they are set to ‘10’. This allows the pipeline to commit the non-CHECK instructions as usual. Irrespective of its func-

---

5 While in modern CPUs the processor can directly access memory, bypassing the cache, to store the result in a register, this approach is not a feasible one because (a) we do not want to load the processor with additional memory accesses, and (b) the data needs to arrive to the module and not to the processor.
tionality, each module has a hardware mechanism to scan the *Fetch_Out* queue in the framework to acquire any CHECK instruction intended for the module.

<table>
<thead>

</tr>
</thead>
</table>
| 0 | 0 | 1. IOQ entry is free.  
   2. IOQ entry is allocated, contains a CHECK instruction, and its execution in the module is not yet complete.  
   3. The pipeline may stall if the instruction is ready for commit. |
| 1 | 1 | 1. IOQ entry is allocated, contains a CHECK instruction and an error is detected from the execution of the CHECK instruction.  
   2. The pipeline commits the instruction as usual.  
   3. IOQ entry is allocated, contains a CHECK instruction and its execution in the module is not yet complete.  
   4. The pipeline may stall if the instruction is ready for commit. |

**Table 1: Diagnostic Role of the CheckValid and Check Fields in IOQ**

As indicated earlier, a module operates in one of two modes. In the *synchronous* mode, the module sets the *checkValid* bit when it completes execution. The pipeline reads the check bits and takes the appropriate action (commit or flush). If the instruction in the pipeline is ready to commit and the module has not yet completed execution, the pipeline waits until the execution is completed in the module and the *checkValid* bit is set. In the asynchronous mode, the module sets the *checkValid* bit of a CHECK instruction entry to ‘1’ immediately after it scans the *Fetch_Out* queue and acquires the CHECK instruction intended for it. The pipeline commits the instruction as usual and sends a signal to the RSE (*Commit_Out*). The module executes independent of the pipeline and on receiving the commit signal from the pipeline, logs the permanent state that it is collecting. Thus the modules are either stateless or independent of the speculative state of the pipeline.

Observe that for a ‘10’ combination of the check bits (*checkValid* and *check* fields) the pipeline commits the instruction as usual. We take advantage of this observation to introduce an enable/disable mechanism for modules (*Module Enable/Disable* unit in Figure 1). Initially, all modules are disabled. A module is enabled by the application using a CHECK instruction that contains a request to enable the module. On a request to disable a module (through a CHECK instruction), the enable/disable unit desensitizes the path from the output of the module to the entry in the IOQ. Instead of the module output, a constant ‘1’ is written to the *checkValid* field and a constant ‘0’ to the *check* field.

**Hardware modules.** The RSE contains hardware modules implementing security support and error-detection mechanisms for protecting the application. These modules are embedded in the framework and execute in parallel with the execution of the instruction stream in the main execution pipeline. Inputs required for execution of the check are acquired by the module from the input interface queues defined above. For *synchronous* operation, the goal is to reduce the impact on the performance of the application by completing the check before the instruction is ready for commit. For *asynchronous* operation, of course, the module can lag behind the pipeline and only perform its operation when the instruction is committed. Irrespective of the functionality of the module, each module has (i) a hardware mechanism to scan the *Fetch_Out* queue in the framework, to acquire any CHECK instruction
intended for this module, and (ii) a memory buffer to hold data accessed from memory or to be stored in memory. In addition, each module has module-specific logic to check for malicious attacks and store check-based information, e.g., thread dependency, or checking for random errors. Figure 1 shows the Instruction Checker Module (ICM), the Memory Layout Randomization (MLR) module, the Data Dependency Tracker (DDT) module, and the Adaptive Heartbeat Monitor module.

3.3 Application Interface: The CHECK Instruction
As indicated, the application interfaces with the engine using special instructions called CHECK instructions. The application is instrumented at compile time to include these special instructions. This requires an extension of the instruction set architecture of the processor. The format of the CHECK instruction includes the following fields:

- **Opcode** – contains the opcode CHK.
- **Module#** – specifies the module that performs the check.
- **BLK/NBLK** – specifies whether the instruction is blocking or nonblocking. Blocking checks produce results used at the commit stage to decide whether the instruction can be retired. If the result is not ready, the commit stage stalls. Blocking CHECK instructions are used for synchronous operation, whereas nonblocking checks are used for asynchronous mode of operation.
- **Config Options** – The encoding of these bits is specific to the module. They are used to (i) invoke a hardware module and (ii) provide additional parameters.
- **Operation** – defines the specific operation to be performed by the module.
- **Parameter** – specifies any parameters required for the operation.

When the main pipeline encounters CHECK instructions, it considers them as NOPs in all stages of the pipeline, except in the retirement or commit stage.

3.4 Self-Checking Mechanisms in RSE
The framework employs a self-checking mechanism to detect its own errors and decouple from the pipeline. The self-checking is based on monitoring the transitions on the check and checkValid bits (as discussed in Table 1). In the following discussion, four error scenarios are considered (see Table 2).

To handle error scenarios outlined in Table 2, a mechanism for self-checking of the RSE framework is proposed. A watchdog monitors the transitions occurring in the output bits of each IOQ entry. Both 0→1 and 1→0 transitions are monitored. If a 0→1 transition does not occur in the checkValid field for a specified number of cycles, a module executing the CHECK instruction in this entry does not make progress or it has a stuck-at-0 fault in the check field. If a 1→0 transition does not occur in the checkValid field for a specified number of cycles, a stuck-at-1 fault is assumed in the checkValid or check field.
In addition, a counter is maintained for each entry in the IOQ to monitor the 0→1 transition (i.e., an error indication) in the check field of that entry. If the transition occurs more than a threshold number of times within a specified interval of time (set equal to the watchdog timeout interval) then the module is declared erroneous.

If the self-checking mechanism declares an error, the framework is decoupled from the main pipeline. This can be achieved by switching to a safe mode in which the output of the framework always allows the pipeline to commit the instruction, by setting the checkValid and check bits to ‘1’ and ‘0’ respectively. The constant outputs can be produced using a simple multiplexer mechanism.

<table>
<thead>
<tr>
<th>Error Scenario</th>
<th>Possible Implications</th>
</tr>
</thead>
<tbody>
<tr>
<td>Module does not make progress</td>
<td>The module does not produce any result. Thus, an instruction in the pipeline can wait forever, forcing the application to hang.</td>
</tr>
<tr>
<td>False Alarm – the module always declares an error</td>
<td>The pipeline is flushed and starts execution repeatedly at the same CHECK instruction in order to recover from the error; the application does not make progress. A burst of errors that set the check field in the IOQ entry can also cause this error scenario.</td>
</tr>
<tr>
<td>False Negative – the module always declares there is no error</td>
<td>The application proceeds with execution and effectively is not receiving any protection from the CHECK instruction executed in that module. A burst of errors that reset the check field in the IOQ entry can also cause this error scenario.</td>
</tr>
<tr>
<td>The output bit (Check or CheckValid) in the IOQ entry is stuck-at-1 or stuck-at-0</td>
<td>Stuck-at-0 of checkValid – equivalent to the scenario where a module does not progress. Stuck-at-0 of check – the output of the framework is irrelevant to the pipeline; application executes without waiting for the result from the module. Stuck-at-1 of check – equivalent to the scenario where the module produces a false negative.</td>
</tr>
</tbody>
</table>

Table 2: Error Scenarios of the RSE Framework

4 Description of Modules in RSE

The following sections discuss the issues in designing the RSE framework (Table 3) and present a detailed description and the experimental evaluation of example hardware modules embedded in the framework.

4.1 Memory Layout Randomization Module

In our earlier study, a software-based approach, the Transparent Runtime Randomization (TRR) [34], was proposed to transparently randomize the memory layout of an application process in order to defeat a large class of security attacks (e.g., buffer overflow, format string and etc.). These attacks, which amount to over 60% of all attacks reported by CERT, are based on an attacker’s knowledge of the memory layout of a target application. In this study, we implement and integrate a hardware Memory Layout Randomization (MLR) module into the RSE framework. This module randomizes the locations of both the position independent and the position dependent memory regions.\(^6\) Hardware implementation of the randomization algorithm has several advantages. (1) The RSE implementation can potentially be used by different operating systems, while our software implementation was always system-specific. Although the memory layouts on Windows and Unix/Linux-based systems are quite different, we propose a simple function call to enable uniform implementation of the MLR across different operating systems. (2) A hardware implementation is more difficult to tamper with than an entirely software one. For ex-

---

\(^6\) Randomization of position dependent regions is discussed in the context of the global offset table (GOT), employed on Linux to keep the function pointers used for dynamic library function calls. The equivalent structure on Windows is called IAT (Import Address Table).
ample, a malicious user can exploit operating system vulnerabilities and compromise a software solution. (3) The RSE implementation can speed up the algorithm, especially useful in re-randomizing for long-running applications.

<table>
<thead>
<tr>
<th>Issue</th>
<th>Description</th>
<th>Proposed Solution, Rationale, Pros and Cons</th>
</tr>
</thead>
</table>
| Overhead introduced in memory hierarchy    | The Memory Access Unit (MAU) serves memory requests on behalf of all the modules in the framework. It uses the same memory interface circuitry as the main pipeline. | Solution: the memory access of the main pipeline and MAU are arbitrated upon, giving a higher priority to the main pipeline in case of a conflict.  
Rationale: choose between (i) accessing L1 Cache; (ii) accessing L2 Cache directly and (iii) accessing main memory directly.  
L1 Cache to processor path is used very frequently by the processor; any delay introduced in this path due to the arbiter will be very prominent (Amdahl's law).  
Cache hit rate is very high for both the L1 and L2 Caches; frequency of accessing the memory to L2 Cache path is relatively low.  
Arbiter in this path would have a much lesser affect on the pipeline execution delay.                                                                 |
| Feedback to the pipeline                   | For blocking CHECK instructions the pipeline waits for the CheckValid signal from the framework to commit the instruction. | Impact of CHECK instruction on the pipeline depends on the module specifics:  
• For the MLR module – the CHECK instruction invokes the module, which is active only during the program initialization; there is no runtime overhead;  
• For the DDT module – the CHECK instruction is only used to enable the module;  
• For the ICM module – the CHECK instruction may stall the pipeline if the check does not finish before the instruction is ready to commit; |
| Fan-out from the pipeline stages           | The extra fan-out from each stage introduces a delay in the pipeline's critical path. | Solution: the output from the pipeline stage is latched into a register and then provided to the circuit in the framework.  
Rationale: Using an intermediate latch provides a constant additional loading to the pipeline outputs, irrespective of the type and number of modules accesses the input.  
Pros and Cons: a constant loading to the pipeline outputs leads to a nearly uniform increase in execution time for each stage; an increased delay in the execution time for each stage increases the clock cycle time; information passed by pipeline is available to the framework only after a delay of one cycle.  
Additional overhead of wires to get outputs. Complexity in locating outputs for each stage in a modern superscalar out-of-order processor. |
| Context switch in the processor            | When a context switch occurs in the system, the framework may be in the process of executing a CHECK instruction. | A context switch is automatically handled.  
Before executing a context switch, the processor waits till all the instructions in the reservation station have completed execution and committed. Thus, all the CHECK instructions in the framework must have been completed and their results forwarded to the processor before the system call for context switch begins execution.  
The framework may contain process-specific state. Currently considered CHECKs are stateless; thus, the framework state does not need to be saved in case of a context switch. |
| Calculation of delays                      | Pipeline to input queue entry delay                                         | The multiplexer feeding the input queue is a combinational circuit with 3 gate-levels and can be evaluated in a single cycle. |
|                                           | Module to output queue delay                                                | Each module can write the output of execution of the CHECK instruction to the corresponding entry in the IOQ. This requires a broadcast mechanism, incurring a delay of 1 cycle. |
|                                           | Module input queue scanning delay                                           | Each module scan the Fetch, Out input queue to scan for CHECK instructions intended for that module. This would incur a delay of 1 cycle. |
| Other delays                               | IOQ entry to commit unit                                                    | Using appropriate routing design techniques this delay can be kept small. |
|                                           | Arbiter delay                                                              | This is the delay due to arbitration of framework and pipeline memory requests. It is accounted for in simulation. |
|                                           | Wiring delay                                                               | The delays due to the additional wires added have to be addressed via efficient circuit design techniques. |

Table 3: Issues in the Design of the Framework

**Implementation of the MLR.** The randomization task is split between the program loader and the MLR module. For ease of implementation, we provide a portable library. The only change is for a loader to call a special library
function. When invoked, the special library function performs the following actions (described in Figure 3(A):
(1) A special header is assembled, which includes information for the position-independent regions (Instruction I0
in Figure 3(A)). The library function extracts information from different parts (the locations are system specific)
of the executable and places them in the special header, which consists of the locations and sizes of text and data
segments, and the starting address of stack and shared libraries. (2) The header is passed (via a CHECK instruc-
tion) to the MLR module, which performs the randomization operations and writes the results to memory locations
specified by the loader. (3) The output produced by the MLR module is used to complete the loading process.

Figure 3(A) shows the code section within the library function that performs the randomization operations and
Figure 3(B) shows the register transfer level operations within the MLR module while performing these opera-
tions. The code section in Figure 3(A) is a mix of RSE CHECK instructions (tagged with \texttt{chk}) and library func-
tion instructions (in shadowed boxes). Instructions I1 through I3 perform the randomization of the position-
independent regions such as stack, heap, and shared libraries. The library first provides the location of the execu-
table header to the MLR and then issues I2 to request the randomization operation. During execution of I2, MLR
reads and parses information from the header and computes the randomized address values for position-
independent regions by adding the value from the clock cycle counter (see Figure 3(B)). The results are written to
predefined memory locations, randomized shared library base, randomized stack segment base, randomized heap
segment basey. The library then executes a series of instructions (pointed to by I3) to create a random mapping
for these regions.

The randomization of the position-dependent region (GOT) is performed by Instructions I4 through I11. It in-
volves the following steps: (1) Executing a series of instructions at I4, the library allocates space for the new GOT
at a random memory location. (2) Executing CHECK instructions I5 and I6, the library passes the address and
size information to the module. CHECK instruction I7 requests the module to copy the old GOT to the new loca-
tion. The module first copies (without any software intervention) the GOT entries to the internal GOT buffer
(shown in Figure 3(B)), and then back to the new location in the memory. (3) Instructions I8 through I11 perform
the rewriting of the program’s procedural linkage table (PLT) so that the entries refer to the new GOT\textsuperscript{7}. First, I8
provides the size and address information of the PLT to the MLR. The library then grants write permission to the
PLT section, after which it issues I10 for the MLR to perform the actual PLT rewriting. The module copies PLT
entries into the PLT buffer, rewrites them to reflect the new location of the GOT, and writes back to the PLT in
the application code segment (see Figure 3(B)).\textsuperscript{8} Finally, the library restores the write permission on the PLT.

\textsuperscript{7} Each PLT entry is an indirect jump to a library function through an entry in the GOT. Thus, rewriting the PLT involves re-
placing the address value in the indirect jump pointing to the old GOT to the corresponding address in the new GOT.

\textsuperscript{8} Because the PLT entries are independent of one another, more than one entry can be rewritten concurrently.
Cache coherency. During process initialization, the loader invokes the MLR module to perform the relocation of the GOT and the rewriting of the PLT. Since the processor has not started execution of the application at this time, there is no conflicting copy of the PLT or the GOT in the processor cache. The application begins execution only after the GOT is relocated and the PLT is rewritten and written back to memory. Hence, cache coherency is not an issue.

Runtime re-randomization. The randomization mechanism is applied to applications at process loading time. For long-running programs, such as server applications, once the process is started, the random memory layout will remain fixed until the program terminates and gets reloaded. From a security perspective, a large window of static behavior can lead to potential vulnerability (e.g., information leak). A better approach is to re-randomize the process as it is running.

The major challenge in re-randomization is to determine what data in a process needs to be re-randomized. Toward this end, we propose to modify the compiler to identify such data elements. When compiling a program, the compiler analyzes the source code to determine which data items are pointer variables. For pointers in static data segment, the compiler records their locations and places the information in a special data section. For dynamically allocated pointer variables in the stack and heap segments, the compiler generates code to place/remove the addresses of these pointers to/from the special memory section at runtime as they are allocated and removed. Periodically, the process is stopped for re-randomization. The re-randomization routine first locates the special data section, then applies a new random offset to data pointed to by this section. The routine then re-maps each memory segment to its new address by applying the new random offset. Finally, the routine resumes execution of the process.

Figure 3: Memory Layout Randomization Module: (A) Instruction Sequence and (B) Architecture

4.2 The Data Dependency Tracking Module

The Memory Layout Randomization Module discussed in the previous section essentially converts a security attack into a program crash. While this prevents a program from being hijacked, the loss of service due to the attack...
is nevertheless undesirable. This is especially true if the server is multithreaded and the entire thread pool has to be killed due to the crash of one faulty thread. The rationale behind the kill-all approach is that, since threads in an application share a single memory address space, there is no guarantee, in case of a malicious thread, that the data shared among the threads is still in a clean and consistent state.

In this section, we describe a hardware module to minimize the impact of a single malicious thread in a multithreaded application. The Data Dependency Tracker (DDT) is proposed for tracking the data dependency among threads and for saving their respective memory pages to provide the information needed to recover the healthy surviving threads. While there are similarities to traditional checkpointing schemes, the difference is in not maintaining a thread’s execution state. The current DDT implementation targets applications whose inter-thread dependencies are due to operations on main memory data structures. This includes many classes of major applications, such as network servers. For example, in the case of a multithreaded Apache web server, threads independently serve web requests, and dependency occurs only when two threads read from and write to the same memory page.

4.2.1 Data Dependency Tracking

The problem from a security perspective is to determine which surviving threads are healthy. A thread is healthy in this context, if and only if the thread is not dependent on the faulty thread. A thread \( t_1 \) is said to depend on \( t_2 \), if \( t_1 \) consumes data produced by \( t_2 \), directly or indirectly. A thread \( t \) is healthy if it does not consume any data produced by the faulty thread. A thread remains healthy if there is no future dependency on the faulty thread. To guarantee a healthy thread’s future independence of the faulty thread, we must undo changes made by the faulty thread. In the context of the RSE, we propose a page-based mechanism for tracking data dependency among different threads in a process.\(^9\)

**Tracking mechanism.** The proposed technique is similar to the copy-on-write mechanism implemented in many operating systems for memory page sharing between processes. The copy-on-write mechanism is implemented by setting a writable page to be read-only and having the processor MMU raise exception when writing is detected at the page. We employ a similar approach to support recovery of memory pages shared by threads in the same virtual memory address space. Each memory page has a read-owner and a write-owner, denoted by the owner thread IDs. Let \( t' \) and \( t'' \) be the read- and write-owners of a page \( p \) respectively. When a thread \( t \) reads the page \( p \) (\( t' \neq t \)), \( t \) becomes the read-owner of \( p \) and a data dependency \( t'' \rightarrow t \) is defined and entered into a Data Dependency Matrix (DDM). Note that \( t'' \) is the producer in the dependency relationship because it last wrote to the page \( p \). Thread \( t \) is the consumer because it reads information produced by \( t'' \). The DDM is an \( N \times N \) matrix, where \( N \) is the number of

\(^9\) Software mechanisms for detecting data dependency, such as debugger-based tracing, can detect word-level fine grain data accesses by different threads through single stepping, but incurs prohibitively high overhead. Also the current thread-based checkpointing work does not quite address the issue.
threads in the process. Each entry \((x, y)\) in the matrix is one bit, which when set to 1 indicates that thread \(y\) is data-dependent on thread \(x\). Note that the dependency relation is transitive but not symmetric. In order to recover a page updated by a faulty thread, it is important to save a copy of the memory page prior to its update by a thread that is not the current write-owner of the page.

A block diagram for the DDT module is shown in Figure 4. The DDT tracks and logs thread dependency in parallel with the execution of memory access instructions in the main pipeline and minimizes the performance impact\(^{10}\). The DDT receives information from the \(\text{Fetch\_Out, Execute\_Out, Commit\_Out}\) input queues in the RSE.

Figure 5 shows the state transition diagram for a memory page’s status. Both \(s\) and \(t\) represent threads. The shaded oval represents the state \((t, s)\): thread \(t\) is the write-owner of the page, and thread \(s\) is the read-owner of the page. Transition between two states is represented by a labeled arrow, which corresponds to an event. An event is a pair \((tid, op)\), where \(tid\) is the ID of a thread that performs operation \(op\). An \(op\) can be either \(r\) (read from) or \(w\) (write to) the page. Three different actions are possible: \(\text{SavePage}\), which saves a copy of the page; \(\log(t \rightarrow s)\), which writes the corresponding entry in the DDM; and a dash (-) representing no action.

The DDT receives memory access instructions from the instruction fetch stage (\(\text{Fetch\_Out}\)). The target memory address for a load or store instruction is received from the instruction execution stage (\(\text{Execute\_Out}\)), where the effective address is computed and converted to a unique \(\text{PageID}\). The DDT maintains two main structures for tracking data dependencies: the page status table (PST) and the data dependency matrix (DDM). Due to memory access locality, only a small number of “hot” pages need to be kept in the PST at any given time, and an LRU replacement policy can be used to improve cache performance. An entry in the PST is the tuple \((\text{PageID, write-owner, read-owner})\), where \(\text{PageID}\) is a unique tag for a memory page, and \(\text{read-owner}\) and \(\text{write-owner}\) are the thread IDs of the read- and write-owners of the memory page. Whenever a dependency is detected in the state transition diagram shown in Figure 5, the corresponding bit in the dependency matrix is set to 1.

If the DDT module is enabled in the framework (via a \(\text{CHECK}\) instruction), it scans the \(\text{Fetch\_Out}\) queue for memory access instructions (\(ld/st\)) and resets the \(\text{checkValid}\) field of the corresponding entries in the IOQ. The operations in the module are done transparent to the pipeline execution, and hence the instruction in the pipeline can commit without waiting for module to complete. In other words, the module can lag behind the pipeline in completing the logging of the dependencies. Let \(t’\) and \(t''\) be the read- and write-owners of the page \(p\) and let the current thread be \(t\). There are four possible outcomes: (1) it is a load instruction and \(t = t’\); (2) it is a load instruction and \(t \neq t’\); (3) it is a store instruction and \(t = t''\); (4) it is a store instruction and \(t \neq t''\). In cases (1) and (3), no operation needs to be performed and the module does not lag behind the pipeline. In case (2), the read-owner field

---

\(^{10}\) The page-based memory dependency-tracking algorithm can also be implemented by changing the structure of the processor memory management unit’s TLB (translation look-aside buffer). The read- and write-owner fields should be added to each TLB entry, and the state transition should be implemented. The problem with the TLB-based approach is that TLB is usually on the critical path for memory access, and the added structural and functional complexity may slow down memory access and the performance of the pipeline.
of the PST entry needs to be changed from $t'$ to $t$, and a dependency $t'' \rightarrow t$ is logged. In this case the module may lag behind the pipeline by at most 1 cycle. If a new load instruction which creates a new dependency arrives within this time the module fails to log the dependency due to this instruction. In case (4) a SavePage exception is generated. The exception is handled by the operating system exception handler, which checkpoints the memory page $p$. The process is suspended, and no subsequent stores can be executed until the entire memory page has been saved. This prevents the possibility of another SavePage exception while the page is being checkpointed.

4.2.2 Issues in DDT Design

**Target applications.** The DDT mechanism targets applications whose interthread dependencies are mainly due to operations on main memory data structures. The memory-based tracking scheme can also be extended to cover these applications, since all file I/O operations must go through memory buffers.

**Safety of saved data.** Currently, all checkpoints are saved in the main memory by the operating system exception handler. It is possible that the operating system itself can be compromised. In light of this possibility, the memory layout randomization approach can be applied to the operating system kernel for masking kernel vulnerabilities. However, we believe that this is not necessary because studies of CERT data show [1] that a relatively small fraction of successful attacks target operating system kernels. Many of these are in fact denial-of-service attacks. Also, hardware memory protection mechanisms ensure that application-level vulnerabilities do not lead to compromise of kernel data structures.

**Garbage collection.** The current scheme saves memory page snapshot in main memory. A natural question to ask is how overflow of the memory buffer can be handled. A solution is to have a kernel thread (independent of the target application threads) that asynchronously flushes the memory pages on the disk. For long-running applications, however, it is possible that even the disk space will be used up. For this, we can either (a) periodically restart the application and remove all previously saved memory pages; or (b) handle the space overflow using a garbage collection algorithm that periodically removes pages from the buffer using a time-based threshold. In order to keep the application state consistent in case of recovery, we keep history information for deleted pages.
When any of the deleted pages is needed for recovery, the recovery algorithm terminates the entire process (i.e., all threads) due to insufficient information.

**Recovery algorithm.** Although DDT tracks thread dependencies and collects information needed for recovery, it does not perform the actual recovery operations. System software performs recovery by retrieving information stored in PST and DDM through a special *size query* and *retrieval* check instruction. The information provided by the DDT is used to recover memory pages and resume execution of surviving threads without execution rollback. The approach leverages existing checkpointing and recovery algorithms for both distributed and multithreaded applications [7][5][13][22]. To minimize application-wide impact of the faulty thread $t_f$, we identify (using information stored in DDM) and terminate all threads that are data-dependent on $t_f$. The memory updates due to $t_f$ and its dependent threads are undone so that they do not impact the future execution of the healthy threads in the process. Due to space limitation, we skip discussion of specifics of the recovery algorithm. The details can be found in [38].

### 4.3 Instruction Checker Module

The Instruction Checker Module (ICM) preemptively checks for errors in an instruction just at the time the instruction is dispatched, by comparing the binary of the instruction in the pipeline with a redundant copy of the instruction fetched from memory. Thus it provides coverage for multiple-bit errors in the instruction from the time the instruction is fetched from memory to when it is dispatched in the pipeline. This includes the period when the instruction is resident in the on-chip caches. The instruction checked can be a control flow, load/store or a critical code section of the application. Thus this approach is complementary to several architectural fault tolerance approaches that effectively employ redundancy in the pipeline in space or in time [16]-[21], [28]. Instructions following a CHECK instruction (*checked instructions*) with module# field set to ICM are checked by the ICM. The program is initially statically parsed, and all the checked instructions are stored in a separate chunk of memory (*CheckerMemory*) in a contiguous manner. The ICM receives the CHECK instruction, the instruction to be checked, and the corresponding program counter from the output of the fetch stage, *Fetch_Out* input. It gets the redundant copy of the instruction from the *CheckerMemory*. To reduce the performance overhead of accessing the *CheckerMemory* a dedicated cache (*Icm_Cache*) is employed within the ICM. The two copies of the instruction, one from the pipeline and one from the *CheckerMemory* (or *Icm_Cache*) are compared. The result (*Instruction MATCH* or *MISMATCH*) is written to the *check* output, and the *checkValid* bit is set.

**Implementation of ICM.** The ICM is designed and implemented as a pipeline. The individual tasks of the ICM form three independent pipeline stages: (1) *ICM_IDLE* scans *Fetch_Out* queue for CHECK instructions and posts a memory request to the MAU for a redundant copy of the instruction, (2) *ICM_MEMREQ* waits for the redundant copy, the two copies are sent to the comparison stage, and (3) *ICM_COMP* – The two copies of the instruction are compared, and the result is written to the instruction output queue (*check* and *checkValid* fields).
Replacement policy for the ICM cache. The replacement policy used for the ICM cache is a least-recently-used (LRU) algorithm implemented using a stack. The contiguous placement of checked instructions in the checker memory makes it easy to fetch multiple checked instructions in a single fetch to provide spatial locality.

Figure 6 depicts the timeline for the execution of the ICM. The time scale in shown to the left. The processor fetches instructions from the memory into its internal cache. Instructions are fetched from the cache into the fetch buffer for execution at time \( t \). The instruction is renamed and allocated in the reorder buffer at time \( t+1 \). Instructions are forwarded from the reservation station to the RSE and arrive at the RSE fetch queue at time \( t+2 \). At this point, the instruction has a unique identifier—the reorder buffer entry number—by which it is addressed throughout its lifetime in the pipeline. This enables the RSE and the pipeline to use the same unique identifier for communication of inputs and outputs of an instruction. The ICM detects the presence of a CHECK instruction in the fetch buffer and stores the following instruction (checked instruction) from the fetch buffer. This is the copy of the instruction executing in the pipeline. The ICM places a request for a redundant copy of the same instruction to the ICM cache. In the case of ICM cache hit, the redundant copy of the instruction is available, and the two copies are sent to the comparator at time \( t+3 \). Results are written to the instruction output queue at time \( t+4 \) and are available to the commit stage of the pipeline at time \( t+5 \). In the case of a miss in the ICM cache, a memory request is placed to fetch the missing instruction. The data received from memory is placed in an internal buffer and then stored to the ICM cache. The latency of memory access depends on the number of bytes being accessed from memory. Memory access in modern microprocessors is pipelined. Therefore, the response time for the first chunk of bytes (size = memory bus width) is usually high, and subsequent chunks are available at shorter intervals.

![Figure 6: Timeline for ICM Execution](image)

4.4 Adaptive Heartbeat Monitor (AHBM)
The Adaptive Heartbeat Monitor (AHBM) is a hardware module in the reliability engine providing features to facilitate easy heartbeating of processes. A block diagram of the module is shown in Figure 7. (1) ENTITY_IDX: A content addressable memory, containing the IDs of the monitored processes or the OS, (2) COUNTER_RAM:
A RAM containing Process Specific Counters. (3) TIMEOUT_MEM: A RAM containing the dynamic timeout values. When the module receives an Increment Counter Value CHECK instruction from a process it updates the counter value for that process.

The AHBM can monitor the operating system through a kernel driver module, which updates a counter in the module at heartbeat intervals. Spawning an additional thread, which issues CHECK instructions for counter update at regular intervals, can check a process.

The Adaptive Timeout Monitor (see Figure 7) samples the counter values for each process after a fixed interval of time and calculates appropriate timeout values dynamically using an adaptive time-out algorithm. Due to space limitations, we do not present the algorithm in this paper.

5 Experimental Setup and Results

In this section, we describe the experimental setup used to evaluate the Reliability and Security Engine and its modules. The experiments can be classified into the following three categories:

1. **Framework Overhead.** The goal is to measure the overhead incurred by the processor due to the presence of the framework without any modules instantiated, i.e., the framework is effectively decoupled from the pipeline. The overhead incurred in the performance of the application is due to the memory arbiter introduced to arbitrate memory accesses of the processor and the RSE.

2. **Cache Performance Overhead.** The goal is to measure performance impact of CHECK instructions inserted into the application by the compiler. These instructions constitute part of the application instruction stream and, as such, are also fetched into the I-Cache, reducing the performance of the cache.

3. **Performance Overhead Due to Modules.** The goal is to measure performance overhead of individual RSE modules. Modules are instantiated one at a time, and the performance overhead incurred by the application is captured.

\[\text{As explained previously, there is an increase in the cycle time due to the additional fan-outs. Nevertheless, the number of cycles for the execution of the application remains the same. The increase in cycle time is not modeled in the current simulator.}\]
5.1 Simulation setup
The *sim-outorder* processor performance simulator of the SimpleScalar Tool Set [4] has been augmented to simulate the RSE with embedded hardware modules. *sim-outorder* simulates an out-of-order pipelined processor. The main loop of the simulator is executed once for each target (simulated) machine cycle. Currently, CHECK instructions are embedded at runtime, not at compile time. When an instruction is fetched, the simulator determines (either by decoding the instruction or by monitoring the fetched instruction address) whether the instruction has to be checked and, if so, inserts a CHECK instruction before it into the instruction stream. This is equivalent to the CHECK instruction being embedded in the static instruction stream of the program. The experiments were performed by running the SPEC200-INT vpr (Placement and Routing) and the *kMeans* application. The *kMeans* application that was used for the evaluation is an implementation of the K-Means clustering algorithm. The K-Means algorithm is a numerical clustering strategy using a predetermined number of clusters, *k*. It is both I/O and computation intensive. The original source code contains 3 iterations, 200 patterns, and 16 clusters which when run on the simulator takes prohibitively long time.

*Cache overhead simulation.* One limitation of simulating CHECK instructions by inserting them at runtime is that this does not consider the performance overhead on the I-Cache due to the additional CHECK instructions. The presence of the CHECK instructions in the fetched instruction stream decreases the performance of the I-Cache, as there are more instructions to be fetched. One way to measure this performance overhead is to insert the CHECK instructions in the actual instruction stream, which requires compiler support. An alternative approach to measuring the cache performance impact is to rewrite the code segment of the process inserting NOP instructions wherever a CHECK instruction has to be placed and running the baseline simulator. A fetch for an instruction from the simulator is redirected to the new code segment. The NOP instructions are also fetched into the I-cache, simulating the effect of the CHECK instructions.

5.2 Results
Table 4 presents the experimental results for the benchmark applications. Row 2 shows the number of cycles (in millions) for the execution of the benchmark on the baseline simulator. Row 3 shows the number of cycles with the simulator augmented with the framework but with no modules instantiated. Row 4 shows the number of cycles with the simulator augmented with the framework including the ICM module. The benchmark is instrumented to check all control-flow instructions. The subsequent rows, 5 and 6, give the percentage overheads for the above two configurations. The next set of rows present the results for the cache performance overhead. The number of accesses and miss rates for the il1 and il2 caches are tabulated.

The framework overhead is attributed to delay of the memory arbiter, which is introduced for arbitration of memory access between the cache and the RSE Manager. Memory access is pipelined, and in the baseline case, the memory access latency for the first chunk is 18 cycles; each of the subsequent chunks arrives 2 cycles after the previous one. The memory access latency for the first chunk and the inter-chunk latency have been changed to 19
and 3 cycles, respectively. In arriving at these numbers, delay due to the arbiter has been assumed to be 1 cycle. The framework overhead is seen to be 3.47% for vpr Placement, 3.64% for vpr route, and 4.99% for kMeans, averaging to 4.03%.

The ICM has been simulated with an ICM_Cache size of 256 and a replacement size of 8 least-recently-used entries. The overhead due to the ICM (combined with that due to the framework) is 11% for vpr placement, 7.7% for the vpr route, and 5.44% for kMeans. The average overhead is 8.1%. Pre-emptive checking, which protects against uncontrolled crashes is expensive [10]. In this context, this overhead is small.

Table 4: Framework Evaluation Results

5.3 Performance and Hardware Overhead of MLR Module

The random relocation of the position-independent regions, i.e., stack and heap, has been implemented in our simulator. The random relocation of the GOT and shared libraries requires support for executable format with dynamically loaded objects from the simulator.

The penalty for position independent regions is fixed and was found to be 56 cycles. Estimating the overhead for the position dependent regions required modification to the simulator. The position dependent part of the algorithm (GOT randomization) is only applicable to dynamically linked executables. SimpleScalar simulator does not support dynamic linking. Extension of the simulator to support dynamic linking (e.g., the dynamic linker on Linux, ld.so-2.2.3, has about 25,000 lines of C code) requires significant effort. Given the goal of the evaluation, i.e., to measure the time it takes for RSE to do the GOT/PLT randomization and to compare that to a pure software implementation, we use a method equivalent to a real dynamic-linking implementation. The proposed approach embeds the dynamic linking mechanism and the randomization algorithm inside a target application, creating an application private dynamic loader. The approach avoids making significant changes in a third-party simulator but allows us to evaluate the performance of the algorithms in a realistic way.
The target program written for the current simulator includes a GOT and a PLT as part of its user data. The program has two versions, one for the pure software implementation and one for the RSE module implementation. In the software version, the program (1) allocates a new copy of the GOT, (2) copies the old GOT to the new GOT, and (3) rewrites every entry of the PLT, and it terminates. The entire process is what a dynamic loader would have done had we used dynamic linking support, except that the process is performed by the program itself. The time it takes for the program to execute is equivalent to the time it takes a dynamic loader to do the GOT/PLT randomization. The RSE version of the program allocates a new copy of the GOT in software and then issues a CHECK instruction to the processor, providing the location of the new GOT, the old GOT, and the PLT. The RSE module, manages the GOT-copying and PLT-rewriting hardware. The module returns control to the program after the randomization is complete.

Table 5 shows the performance evaluation results from using the approach outlined. The performance is evaluated using the number of cycles for the execution of the program as shown in the \#cycle columns. The TRR columns show the result for the pure software implementation of the TRR algorithm, while the RSE columns show the results for the MLR module. The performance improvement from the TRR version to the RSE version is about 20-30% over the different numbers of GOT entries. This improvement is attributed to the fact that fewer instructions need to be fetched and executed to carry out the randomization algorithm in the TRR case. This is because in the software case, the GOT-copying and PLT-rewriting involves a loop for each entry of the table and requires many instructions to be executed multiple times, while in the RSE case, only a few CHECK instructions are needed to carry out the entire task, saving memory and cache bandwidth. It should be noted that the goal is to randomize the memory layout of the process each time it is loaded; hence performance overhead is incurred only during the initialization of the process when the segments of the process are set up. No overhead is incurred during the normal execution of the process.

The hardware required for the MLR module for randomization of position-independent regions (from Figure 3) is 24 word-length registers, 4 adders, and a 4KB memory block for holding the executable header (4KB will accommodate any header for any operating system and file format). Also, the hardware requirements for the randomization of the position-dependent regions are a 4KB memory block to hold the GOT table, a second 4KB memory block to hold the PLT Table, 5 adders, and 2 word-length registers. The details of the implementation are not given in this document due to lack of space, but a point to note is that 4 adders are used to update the PLT Table entries in parallel, 4 entries at a time.

5.4 Performance Evaluation of the DDT

To implement the Data Dependency Tracking module, the simulator is augmented to enable execution of multithreaded applications with networking capabilities. The performance overhead of the DDT is measured using a multithreaded network server, depicted in Figure 8, which shows an example scenario involving five threads. Here $t_2$ writes to page $p1$, $t_1$ subsequently reads $p1$, which causes the dependency $t_2\rightarrow t_1$. Similarly, $t_1\rightarrow t_0$ because $t_0$ reads the page $p2$ written by $t_1$, and $t_0\rightarrow t_1$ because they are related by page $p3$. Let $t_2$ be the faulty thread. When $t_2$ crashes at the checkmark (x), $t_0$ and $t_1$ are dependent on $t_2$. The recovery algorithm will terminate $t_0$, $t_1$, and $t_2$, undo any memory updates by these three threads, and continue executing the remaining two threads, $t_3$ and $t_4$, from where they are last suspended by the scheduler. The recovery line in this case is only for the two surviving threads. Recall that, the memory read and write operations are a high level abstraction to define and monitor dependency among threads. In the Figure 8, $t_3$ writes to a common queue/list and $t_4$ reads and updates the queue, $t_0$ subsequently reads and update the queue, $t_1$ reads the queue again. It is also important to note that the set of threads that are dependent on a violating threads is often a function of timing order of different events in a system. For example, it is possible that $t_3$ and $t_4$ reads page $p3$ before $t_2$ crashes, in which case all threads in the example are dependent on $t_2$ and should be killed.

We vary the number of threads and measure the time for the server to handle one hundred requests. The measurements are shown in Figure 9. The bottom two curves show the execution time with and without DDT support. In both cases, the running time decreases as more threads are added to the pool, and it stabilizes when four or more threads are in the system. Adding more threads allows exploiting more I/O parallelism in thread execution (initial decrease in execution time). After the number of active thread reaches a threshold (four in our simulation) beyond which no more parallelism can be exploited, the thread scheduling overhead comes to play, and addition of new threads does not change the execution time. The performance overhead of DDT, as compared with the baseline case, while initially low, climbs to about 7-8% after most of the thread parallelism is exploited. This overhead is mainly due to saving memory pages. The top curve shows the number of memory pages saved during the execution. This number is small initially and increases when more threads are added, since more instances of sharing are possible when threads compete for jobs.
6 Conclusions

This paper introduces RSE, an architectural framework for providing security and reliability support without sacrificing performance. The framework: (i) hosts hardware modules that provide reliability and security services and (ii) implements input/output interface between the modules and the main pipeline and between the modules and the executing software (operating system and application). The paper describes in detail the RSE architecture, discusses hardware issues (e.g., implications to the main pipeline) in designing the framework and then introduces hardware modules for security and reliability services. Simulation is used to evaluate the performance of the proposed solution. The performance results indicate that hardware solutions provide low overhead mechanisms for protecting against a broad range of security vulnerabilities and accidental error. Further work will focus on incorporating new security and reliability hardware support and translating the simulated architecture into a real hardware implementation.
