TIME INTEGRATION OF TENSOR TRAINS

CHRISTIAN LUBICH†, IVAN V. OSELEDETS‡¶, AND BART VANDEREYCKEN§

Abstract. A robust and efficient time integrator for dynamical tensor approximation in the
tensor train or matrix product state format is presented. The method is based on splitting
the projector onto the tangent space of the tensor manifold. The algorithm can be used for updating
time-dependent tensors in the given data-sparse tensor train / matrix product state format and
for computing an approximate solution to high-dimensional tensor differential equations within this
data-sparse format. The formulation, implementation and theoretical properties of the proposed
integrator are studied, and numerical experiments with problems from quantum molecular dynamics
and with iterative processes in the tensor train format are included.

Key words. Tensor train, matrix product state, low-rank approximation, time-varying tensors,
tensor differential equations, splitting integrator.

1. Introduction. In recent years there has been much interest in the develop-
ment of data-sparse tensor formats for high-dimensional problems ranging from
quantum mechanics to information retrieval; see, e.g., the monograph [4] and refer-
ces therein. A very promising tensor format is provided by tensor trains [24], which
are known as matrix product states in the physical literature [25, 28]. In the present
paper we deal with the problem of updating approximations to time-dependent large
tensors within the data-sparse tensor train (TT) / matrix product state (MPS) for-
mat. This concerns situations where approximations in the TT/MPS format to given
time-dependent tensors in a less data-sparse format are to be computed, as well as
situations where the time-dependent tensor to be approximated in the TT/MPS for-
mat is determined implicitly as the solution of a tensor differential equation, which
would typically arise from a space discretization of a high-dimensional evolutionary
partial differential equation.

In the time-continuous setting, such problems are approached by projecting the
time derivative onto the tangent space of the approximation manifold at the cur-
rent approximation. This is known as the Dirac–Frenkel time-dependent variational
principle in physics; see [15] [16]. This approach leads to differential equations on
the approximation manifold. In our case this manifold consists of tensor trains of a
fixed rank, see [10] for a discussion of this manifold and its tangent space. The time-
derpendent approximation approach on fixed-rank tensor train manifolds is studied
in [15], where the differential equations are derived and their approximation proper-
ties are analyzed. We further refer to [6] for a discussion of time-dependent matrix
product state approximations in the physical literature.

A conceptually related, but technically simpler situation arises in the dynamical
low-rank approximation of matrices [13]. There, the time-dependent variational prin-
ciple is applied on manifolds of matrices of a fixed rank, in order to update low-rank
approximations to time-dependent large data matrices or to approximate solutions
to matrix differential equations by low-rank matrices. The arising differential equations for the low-rank factorization need to be solved numerically, which becomes a challenge in the (often occurring) presence of small singular values in the approximation. While standard numerical integrators such as explicit or implicit Runge–Kutta methods then perform poorly, a novel splitting integrator proposed and studied in [17] shows robustness properties under ill-conditioning that are not shared by any standard numerical integrator. The integrator of [17] is based on splitting the orthogonal projector onto the tangent space of the low-rank matrix manifold. It provides a simple, computationally efficient update of the low-rank factorization in every time step.

In the present paper we extend the projector-splitting integrator of [17] from the matrix case to the tensor train case in the time-dependent approximation.

After collecting the necessary prerequisites on tensor trains / matrix product states in Section 2, we study the orthogonal projection onto the tangent space of the fixed-rank TT/MPS manifold in Section 3. We show that the projector admits an additive decomposition of a simple structure. In Section 4 we formulate the algorithm for the splitting integrator based on the decomposition of the projector. In Section 5 we show that this integrator inherits from the matrix case an exactness property that gives an indication of the remarkable robustness of the integrator in the presence of small singular values. In Section 6 we discuss details of the implementation and present numerical experiments from quantum dynamics and from the application of small singular values. In Section 6 we discuss details of the implementation and present numerical experiments from quantum dynamics and from the application of the integrator to iterative processes in the TT/MPS format.

2. Tensor trains / matrix product states: prerequisites. We present the tensor train (TT) or matrix product states (MPS) formats, together with their normalized representations that we will use throughout the paper. Although our presentation is self-contained, its content is not original and can be found in, e.g., [24, 10].

2.1. Notation and unfoldings.

Norm and inner product of tensors. The norm of a tensor $X \in \mathbb{R}^{n_1 \times \cdots \times n_d}$, as considered here, is the Euclidean norm of the vector $x$ that carries the entries $X(\ell_1, \ldots, \ell_d)$ of $X$. The inner product $\langle X, Y \rangle$ of two tensors $X, Y \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is the Euclidean inner product of the two corresponding vectors $x$ and $y$.

Unfolding and reconstruction. The $i$th unfolding of a tensor $X \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is the matrix $X^{(i)} \in \mathbb{R}^{(n_1 \cdots n_i) \times (n_{i+1} \cdots n_d)}$ that aligns all entries $X(\ell_1, \ldots, \ell_d)$ with fixed $\ell_1, \ldots, \ell_i$ in a row of $X^{(i)}$, and rows and columns are ordered colexicographically. The inverse of unfolding is reconstructing, which we denote as

$$X = \text{Ten}_i(X^{(i)}),$$

that is, tensor $X \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ has the $i$th unfolding $X^{(i)} \in \mathbb{R}^{(n_1 \cdots n_i) \times (n_{i+1} \cdots n_d)}$.

TT/MPS format. A tensor $X \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is in the TT/MPS format if there exist core tensors $C_i \in \mathbb{R}^{r_{i-1} \times n_i \times r_i}$ with $r_0 = r_d = 1$ such that

$$X(\ell_1, \ldots, \ell_d) = \sum_{j_1=1}^{r_1} \cdots \sum_{j_{d-1}=1}^{r_{d-1}} C_1(1, \ell_1, j_1) \cdot C_2(j_1, \ell_2, j_2) \cdots C_d(j_{d-1}, \ell_d, 1)$$

for $\ell_i = 1, \ldots, n_i$ and $i = 1, \ldots, d$. Equivalently, we have

$$X(\ell_1, \ldots, \ell_d) = C_1(\ell_1) \cdots C_d(\ell_d),$$

where the $r_{i-1} \times r_i$ matrices $C_i(\ell_i)$ are defined as the slices $C_i(:, \ell_i,:)$.
Observe that $X$ can be parametrized by $\sum_{i=1}^{d} n_{i}r_{i-1}r_{i} \leq dNR^2$ degrees of freedom, where $N = \max\{n_{i}\}$ and $R = \max\{r_{i}\}$. In high-dimensional applications where TT/MPS tensors are practically relevant, $R$ is constant or only mildly dependent on $d$. Hence for large $d$, one obtains a considerable reduction in the degrees of freedom compared to a general tensor of size $N^d$.

**Left and right unfoldings.** For any core tensor $C_i \in \mathbb{R}^{r_{i-1} \times n_i \times r_i}$, we denote

$$C_i^\leq = \begin{bmatrix} C_i(:,:,1,1) \\ \vdots \\ C_i(:,:,n_i,1) \end{bmatrix} \in \mathbb{R}^{r_{i-1} \times n_i \times r_i}, \quad C_i^\geq = \begin{bmatrix} C_i(:,:,1)^\top \\ \vdots \\ C_i(:,:,r_i)^\top \end{bmatrix} \in \mathbb{R}^{(r_i n_i) \times r_{i-1}}.$$

The matrix $C_i^\leq$ is called the left unfolding of $C_i$ and $C_i^\geq$ is the right unfolding.

**TT/MPS rank.** We call a vector $r = (r_1, \ldots, r_{d-1}, 1)$ the TT/MPS rank of a tensor $X \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ if

$$\text{rank } X^{(i)} = r_i, \quad (i = 1, \ldots, d-1).$$

In case $r_i \leq \min\{\prod_{j=1}^{i} n_j, \prod_{j=i+1}^{d} n_j\}$, this implies that $X$ can be represented in the TT/MPS format with core tensors $C_i \in \mathbb{R}^{r_{i-1} \times n_i \times r_i}$ of full multi-linear rank, that is,

$$\text{rank } C_i^\leq = r_i \quad \text{and} \quad \text{rank } C_i^\geq = r_{i-1}, \quad (i = 1, \ldots, d).$$

In addition, it is known (see [10, Lem. 4]) that for fixed $r$ such a full-rank condition on the core tensors implies that the set

$$\mathcal{M} = \{X \in \mathbb{R}^{n_1 \times \cdots \times n_d} : \text{TT/MPS rank of } X \text{ is } r\}$$

is a smooth embedded submanifold in $\mathbb{R}^{n_1 \times \cdots \times n_d}$.

**Partial products.** Define the left partial product $X_{\leq i} \in \mathbb{R}^{n_1 \times \cdots \times n_i \times r_i}$ as

$$X_{\leq i}(\ell_1, \ldots, \ell_i,:) = C_1(\ell_1) \cdots C_i(\ell_i)$$

and the right partial product $X_{\geq i+1} \in \mathbb{R}^{n_{i+1} \times \cdots \times n_d \times r_i}$ as

$$X_{\geq i+1}(\ell_{i+1}, \ldots, \ell_d,:) = C_{i+1}(\ell_{i+1}) \cdots C_d(\ell_d).$$

See also Fig. 2.1(a) for their graphical representation in terms of a tensor network.

Let a particular unfolding of each of these partial products be denoted as

$$X_{\leq i} \in \mathbb{R}^{(n_1 \cdots n_i) \times r_i}, \quad X_{\geq i+1} \in \mathbb{R}^{(n_{i+1} \cdots n_d) \times r_i}.$$

The obvious elementwise relation $X(\ell_1, \ldots, \ell_d) = X_{\leq i}(\ell_1, \ldots, \ell_i)X_{\geq i+1}(\ell_{i+1}, \ldots, \ell_d)$ then translates into

$$X^{(i)} = X_{\leq i}X_{\geq i+1}^\top.$$

**Recursive construction.** We note the recurrence relations

$$X_{\leq i} = (I_{n_i} \otimes X_{\leq i-1})C_i^\leq \quad (i = 1, \ldots, d) \quad (2.2)$$

starting from $X_{\leq 0} = 1$, and

$$X_{\geq i} = (X_{\geq i+1} \otimes I_{n_i})C_i^\geq \quad (i = 1, \ldots, d) \quad (2.3)$$
with $X_{d+1} = 1$. Here $\otimes$ denotes the standard Kronecker product.

Combining the above formulas we note

$$X^{(i)} = (I_{n_i} \otimes X_{\leq i-1})C_{i}^{<}X_{\geq i+1}^{T},$$

(2.4)

which will be an important formula later. Using the recurrence relations for $X_{\geq i}$ we also obtain

$$X^{(i-1)} = X_{\leq i-1}C_{i}^{>}(X_{\geq i+1} \otimes I_{n_i})^{T},$$

(2.5)

which together with the previous formula allows us the passage from the $(i-1)$th to the $i$th unfolding.

### 2.2. Left and right orthogonalizations.

Thanks to the recursive relations (2.2) and (2.3), it is possible to compute the QR decompositions of the matrices $X_{\leq i}$ and $X_{\geq i}$ efficiently.

Let us explain the case for $X_{\leq i}$ in detail. First, compute a QR factorization (the $\leq$ in $Q_{i}^{<}$ is just notational for now but will become clear in (2.3)),

$$X_{\leq 1} = C_{1}^{<} = Q_{1}^{<}R_{1}, \quad \text{with} \quad Q_{1}^{<}Q_{1}^{\top} = I_{r_{1}}, \quad Q_{1}^{<} \in \mathbb{R}^{n_{1} \times r_{1}}, \quad R_{1} \in \mathbb{R}^{r_{1} \times r_{1}},$$

and insert it into the recurrence relation (2.2) to obtain

$$X_{\leq 2} = (I_{n_{2}} \otimes Q_{1}^{<}R_{1})C_{2}^{<} = (I_{n_{2}} \otimes Q_{1}^{<})(I_{n_{2}} \otimes R_{1})C_{2}^{<}.$$

Next, make another QR decomposition

$$(I_{n_{2}} \otimes R_{1})C_{2}^{<} = Q_{2}^{<}R_{2}, \quad \text{with} \quad Q_{2}^{<}Q_{2}^{\top} = I_{r_{2}}, \quad Q_{2}^{<} \in \mathbb{R}^{(r_{1}n_{2}) \times r_{2}}, \quad R_{2} \in \mathbb{R}^{r_{2} \times r_{2}},$$

so that we have obtained a QR decomposition of

$$X_{\leq 2} = Q_{\leq 2}R_{2} \quad \text{with} \quad Q_{\leq 2} = (I_{n_{2}} \otimes Q_{1}^{<})Q_{2}^{<}.$$

These orthogonalizations can be continued in the same way for $i = 2, 3, \ldots$. Putting $Q_{\leq 0} = 1$, we have obtained for each $i = 1, \ldots, d$ the QR decompositions

$$X_{\leq i} = Q_{\leq i}R_{i} \quad \text{with} \quad Q_{\leq i} = (I_{n_{i}} \otimes Q_{\leq i-1})Q_{i}^{<}$$

where the matrices $Q_{i}^{<} \in \mathbb{R}^{(r_{i-1}n_{i}) \times r_{i}}$ and $R_{i} \in \mathbb{R}^{r_{i} \times r_{i}}$ are obtained recursively from QR decompositions of lower-dimensional matrices $(I_{n_{i}} \otimes R_{i-1})C_{i}^{<} = Q_{i}^{<}R_{i}$. We call the left partial product $X_{\leq i}$ in that case left-orthogonalized.

In a completely analogous way, we can obtain a right-orthogonalized $X_{\geq i}$ as follows. Denote $Q_{\geq d+1} = 1$. Then, starting with $X_{\geq d} = C_{d}^{>} = Q_{d}^{>}R_{d}$, we can use (2.3) to obtain the QR decompositions

$$X_{\geq i} = Q_{\geq i}R_{i} \quad \text{with} \quad Q_{\geq i} = (Q_{\geq i+1} \otimes I_{n_{i}})Q_{i}^{>}.$$
Hence, after a QR decomposition with (2.5), we obtain using (2.4) and the left unfolding of the factor the following SVD-like decomposition

\[ X^{(i)} = Q_{\leq i} S_i Q_{\geq i+1}^T, \quad \text{with} \quad S_i = R_i R_{i+1}^T \in \mathbb{R}^{r_i \times r_i}. \] (2.6)

The matrix \( S_i \) can be chosen diagonal, although we do not insist that it is. Since the orthonormal matrices \( Q_{\leq i} \) and \( Q_{\geq i+1} \) satisfy the recursive relations as explained before, we call (2.6) a **recursive SVD of \( X^{(i)} \)**, or the \( i \)th recursive SVD of \( X \). The graphical representation of such a recursive SVD is depicted in Fig. 2.1(b).

The recursive nature becomes especially apparent in the SVD of \( X^{(i+1)} \). Interpret the factor \( Q_{i+1}^c \) from the QR decomposition as the right unfolding of a tensor \( Q_{i+1} \in \mathbb{R}^{r_{i+1} \times n_{i+1} \times r_{i+1}} \). By identifying

\[ X^{(i+1)} = Q_{\leq i} S_i Q_{\geq i+1}^T = (Q_{\leq i} S_i) Q_{\geq i+1}^T (Q_{\geq i+2} \otimes I_{n_{i+1}})^T \] (2.7)

with (2.5), we obtain using (2.4) and the left unfolding of \( Q_{i+1} \) that

\[ X^{(i+1)} = (I_{n_{i+1}} \otimes Q_{\leq i} S_i) Q_{\geq i+1}^c Q_{\geq i+2}^T = (I_{n_{i+1}} \otimes Q_{\leq i}) (I_{n_{i+1}} \otimes S_i) Q_{\geq i+1}^c Q_{\geq i+2}^T. \] (2.8)

Hence, after a QR decomposition

\[ (I_{n_{i+1}} \otimes S_i) Q_{\geq i+1}^c = Q_{\geq i+1}^c S_i, \] (2.9)

we obtain the \( (i + 1) \)th recursive SVD

\[ X^{(i+1)} = Q_{\leq i+1} S_{i+1} Q_{\geq i+2}^T, \quad \text{with} \quad Q_{\leq i+1} = (I_{n_{i+1}} \otimes Q_{\leq i}) Q_{\geq i+1}^c. \]

A similar relation holds between \( X^{(i)} \) and \( X^{(i-1)} \). Let

\[ X^{(i)} = Q_{\leq i} S_i Q_{\geq i+1}^T = (I_{n_i} \otimes Q_{\leq i-1}) Q_i^c (Q_{\geq i+1} S_i^T), \] (2.10)

then using the QR decomposition

\[ (S_i^T \otimes I_{n_i}) Q_i^c = Q_i^c S_i \]

we can write

\[ X^{(i-1)} = Q_{\leq i-1} S_i Q_{\geq i}^T \quad \text{where} \quad Q_{\geq i} = (Q_{\geq i+1} \otimes I_{n_i}) Q_i^c. \] (2.11)
3. Orthogonal projection onto the tangent space. Let $\mathcal{M}$ be the embedded manifold of tensors of a given TT/MPS rank $r$; see (2.1). In this section, we derive an explicit formula for the orthogonal projection onto the tangent space $T_X\mathcal{M}$ at $X \in \mathcal{M}$,

$$P_X : \mathbb{R}^{n_1 \times \cdots \times n_d} \to T_X \mathcal{M}.$$  

With the Euclidean inner product, the projection $P_X(Z)$ for arbitrary $Z \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ has the following equivalent variational definition:

$$\langle P_X(Z), \delta X \rangle = \langle Z, \delta X \rangle \quad \forall \delta X \in T_X \mathcal{M}.$$  

Before we state the theorem, we recall a useful parametrization of $T_X\mathcal{M}$ as introduced in [10]. Let $X \in \mathcal{M}$ be left orthogonal, that is, for $i = 1, \ldots, d - 1$ we have

$$X^{(i)} = (I_{n_i} \otimes X_{\leq i-1}) C^{\leq}_i X^T_{\geq i+1}, \quad \text{s.t. } X^T_{\leq i} X_{\leq i} = I_{n_i} \quad \text{and} \quad C^{\leq}_i C^{<}_i = I_{r_i}. \quad (3.1)$$  

Define then for $i = 1, \ldots, d - 1$ the subspaces

$$\mathcal{V}_i = \{ \text{Ten}_i \left[ (I_{n_i} \otimes X_{\leq i-1}) \delta C^{\leq}_i X^T_{\geq i+1} \right] : \delta C^{\leq}_i \in \mathbb{R}^{r_i \times n_i \times r_i} \text{ s.t. } C^{\leq}_i C^{\leq}_i = 0 \}$$

and also the subspace

$$\mathcal{V}_d = \{ \text{Ten}_d \left[ (I_{n_d} \otimes X_{\leq d-1}) \delta C^{<}_d \right] : \delta C^{<}_d \in \mathbb{R}^{r_d \times n_d \times r_d} \}.$$  

Observe that these subspaces represent the first-order variations in $C_i$ in all the representations (3.1) together with the so-called gauge conditions $C^{\leq}_i C^{\leq}_i = 0$ when $i \neq d$; there is no gauge condition for $i = d$. Now, [10, Thm. 2] states that

$$T_X \mathcal{M} = \mathcal{V}_1 \oplus \mathcal{V}_2 \oplus \cdots \oplus \mathcal{V}_d.$$  

In other words, every $\delta X \in T_X \mathcal{M}$ admits the unique orthogonal decomposition

$$\delta X = \sum_{i=1}^{d-1} \delta X_i, \quad \text{with } \delta X_i \in \mathcal{V}_i, \quad \text{and } \langle \delta X_i, \delta X_j \rangle = \delta_{ij}.$$  

Now we are ready to state the formula for $P_X$. It uses the orthogonal projections onto the range of $X_{\leq i}$, denoted as $P_{\leq i}$, and onto the range of $X_{\geq i}$, denoted as $P_{\geq i}$. With the QR decompositions $X_{\leq i} = Q_{\leq i} R_i$ and $X_{\geq i} = Q_{\geq i} R_i$, these projections become

$$P_{\leq i} = Q_{\leq i} Q_{\leq i}^T, \quad \text{and} \quad P_{\geq i} = Q_{\geq i} Q_{\geq i}^T.$$  

We set $P_{\leq 0} = 1$ and $P_{\geq d+1} = 1$.

**THEOREM 3.1.** Let $\mathcal{M}$ be the manifold of fixed rank TT/MPS tensors. Then, the orthogonal projection onto the tangent space of $\mathcal{M}$ at $X \in \mathcal{M}$ is given by

$$P_X(Z) = \sum_{i=1}^{d-1} \text{Ten}_i \left[ (I_{n_i} \otimes P_{\leq i-1}) Z^{(i)} P_{\geq i+1} - P_{\leq i} Z^{(i)} P_{\geq i+1} \right] + \text{Ten}_d \left[ (I_{n_d} \otimes P_{\leq d-1}) Z^{(d)} \right].$$

---

The orthogonality of the $\mathcal{V}_i$ spaces is only implicitly present in [10, Thm. 2]; it is however not difficult to prove it explicitly thanks to the left-orthogonalization and the gauge conditions.
for any $Z \in \mathbb{R}^{n_1 \times \cdots \times n_d}$.

Proof. We assume that $X$ is given as (3.1). For given $Z \in \mathbb{R}^{n_1 \times \cdots \times n_d}$, we aim to determine $\delta U = P_X(Z) \in T_X M$ such that

$$
\langle \delta U, \delta X \rangle = \langle Z, \delta X \rangle \quad \forall \delta X \in T_X M.
$$

Writing $\delta U = \sum_{j=1}^{d} \delta U_j$ with $\delta U_j \in V_j$, this means that we need to determine matrices $\delta B_j^< \in \mathbb{R}^{n_{j+1} \times n_j}$ in the unfoldings

$$
\delta U_j^{(j)} = (I_{n_j} \otimes X_{j-1}) \delta B_j^< X^\top_{j+1},
$$

such that the gauge conditions are satisfied

$$
C_j^{<\top} \delta B_j^j = 0 \quad (j = 1, \ldots, d - 1).
$$

Fix an $i$ between 1 and $d$. Since $V_i$ is orthogonal to $V_j$ when $j \neq i$, choosing any $\delta X = \delta X_i \in V_i$ in (3.2) implies

$$
\langle \delta U_i, \delta X_i \rangle = \langle Z, \delta X_i \rangle \quad \forall \delta X_i \in V_i
$$

Parametrize $\delta X_i \in V_i$ as

$$
\delta X^{(i)} = (I_{n_i} \otimes X_{\leq i-1}) \delta C_i^< X^\top_{i+1}
$$

with $\delta C_i^<$ satisfying the gauge condition for $i \neq d$. Then, the left-hand side of (3.3) becomes

$$
\langle Z, \delta X_i \rangle = \langle Z^{(i)}, \delta X^{(i)} \rangle
= \langle (I_{n_i} \otimes X_{\leq i-1})^\top Z^{(i)} X_{\geq i+1}, \delta C_i^< \rangle,
$$

Hence, for all matrices $\delta C_i^<$ satisfying the gauge conditions, we must have

$$
\langle \delta B_i^< X^\top_{i+1} X_{\geq i+1}, \delta C_i^< \rangle = \langle (I_{n_i} \otimes X_{\leq i-1})^\top Z^{(i)} X_{\geq i+1}, \delta C_i^< \rangle,
$$

which implies, with $P_i^<$ the orthogonal projector onto the range of $C_i^<$ for $i = 1, \ldots, d$ and with $P_i^< = 0$ for $i = d$,

$$
\delta B_i^< = (I_i - P_i^<)(I_{n_i} \otimes X_{\leq i-1})^\top Z^{(i)} X_{\geq i+1}(X^\top_{i+1} X_{\geq i+1})^{-1},
$$

where $I_i = I_{n_i, r_{i-1}}$. Inserting this expression into the formula for $\delta U_i^{(i)}$ gives us

$$
\delta U_i^{(i)} = (I_{n_i} \otimes X_{\leq i-1})(I_i - P_i^<)(I_{n_i} \otimes X_{\leq i-1})^\top Z^{(i)} X_{\geq i+1}(X^\top_{i+1} X_{\geq i+1})^{-1} X^\top_{i+1}.
$$

Since $P_{\leq i-1} = X_{\leq i-1} X^\top_{\leq i-1}$, $P_{\leq i} = (I_{n_i} \otimes X_{\leq i-1}) P_i^< (I_{n_i} \otimes X_{\leq i-1})^\top$ and $P_{\geq i+1} = X_{\geq i+1}(X^\top_{\geq i+1} X_{\geq i+1})^{-1} X^\top_{\geq i+1}$, this simplifies to

$$
\delta U_i^{(i)} = (I_{n_i} \otimes P_{\leq i-1} - P_i^<) Z^{(i)} P_{\geq i+1} \quad (i = 1, \ldots, d - 1),
$$

$$
\delta U_d^{(d)} = (I_{n_d} \otimes P_{\leq d-1}) Z^{(i)}.
$$
Now $\delta U = \sum_{i=1}^d \delta U_i$ satisfies the projection condition (3.2). \begin{flushright} $\square$ \end{flushright}

Although the formula in Theorem 3.1 lends itself well to practical implementation, its cumbersome notation is a nuisance. We therefore introduce a simpler notation for the forthcoming derivations.

**Corollary 3.2.** For $i = 0, \ldots, d + 1$, define the orthogonal projectors

$$P_{\leq i} : \mathbb{R}^{n_1 \times \cdots \times n_d} \to TX\mathcal{M}, \quad Z \mapsto \text{Ten}_i(P_{\leq i} Z^{(i)})$$

$$P_{\geq i} : \mathbb{R}^{n_1 \times \cdots \times n_d} \to TX\mathcal{M}, \quad Z \mapsto \text{Ten}_{i-1}(Z^{(i-1)} P_{\geq i}).$$

Then, the projector $P_\chi$ in Theorem 3.1 satisfies

$$P_\chi = \sum_{i=1}^{d-1} (P_{\leq i-1} P_{\geq i+1} - P_{\leq i} P_{\geq i+1}) + P_{\leq d-1} P_{\geq d+1}.$$ In addition, $P_{\leq i}$ and $P_{\geq j}$ commute for $i < j$.

**Proof.** The fact that $P_{\leq i}$ commutes with $P_{\geq j}$ follows from the observation that for any $Z \in \mathbb{R}^{n_1 \times \cdots \times n_d}$, $P_{\leq i}(Z)$ acts on the rows of $Z^{(i)}$—and hence also on the rows of $Z^{(j)}$—while $P_{\geq j}(Z)$ acts on the columns of $Z^{(j)}$.

To write $P_\chi$ using the new notation, we need to work out the term

$$P_{\geq i+1}(P_{\leq i-1}(Z)) = P_{\geq i+1}[\text{Ten}_{i-1}(P_{\leq i-1} Z^{(i-1)})] = \text{Ten}_i[Y^{(i)} P_{\geq i+1}],$$

with $Y = \text{Ten}_{i-1}(P_{\leq i-1} Z^{(i-1)})$. Denote the mode-1 matricization a tensor by $\cdot$. Then, define the tensors $\hat{Z}$ and $\hat{Y}$, both of size $(n_1 \cdots n_{i-1}) \times n_i \times \cdots \times n_d$, such that $\hat{Z}^{(1)} = Z^{(i-1)}$ and $\hat{Y}^{(1)} = Y^{(i-1)}$. In addition, let $\times_1$ denote the mode-1 multilinear product of a matrix with a tensor; see [14] §2.5. Then, using [14] p. 426 to compute matricizations of multilinear products, we get

$$(\hat{Z} \times_1 P_{\leq i-1})^{(1)} = P_{\leq i-1} \hat{Z}^{(1)} = P_{\leq i-1} Z^{(i-1)} = Y^{(i-1)}.$$

Hence, we see that $\hat{Y} = \hat{Z} \times_1 P_{\leq i-1}$. Using the notation $(i,2) = (i,1)^T$ (see again [14] §2.4), we obtain

$$\hat{Y}^{(1,2)} = (\hat{Z} \times_1 P_{\leq i-1})^{(1,2)} = (I_{n_1} \otimes P_{\leq i-1}) \hat{Z}^{(1,2)}.$$

Now, observe that because of the colex ordering of unfoldings and matricizations, we have $\hat{Z}^{(1,2)} = Z^{(i)}$ and $\hat{Y}^{(1,2)} = Y^{(i)}$ and this gives

$$P_{\geq i+1}(P_{\leq i-1}(Z)) = \text{Ten}_i[Y^{(i)} P_{\geq i+1}] = \text{Ten}_i[(I_{n_1} \otimes P_{\leq i-1}) Z^{(i)} P_{\geq i+1}].$$

The term $P_{\leq i} P_{\geq i+1}$ is straightforward, and this finishes the proof. \begin{flushright} $\square$ \end{flushright}

**4. Projector-splitting integrator.** We now consider the main topic of this paper: a numerical integrator for the dynamical TT/MPS approximation

$$\dot{Y}(t) = P_{Y(t)}(\dot{A}(t)), \quad Y(t_0) = Y_0 \in \mathcal{M}$$

of a given time-dependent tensor $A(t) \in \mathbb{R}^{n_1 \times \cdots \times n_d}$.

Our integrator is a Lie–Trotter splitting of the vector field $P_Y(\dot{A})$. The splitting itself is suggested by the sum in Corollary 3.2 using $Y$ in the role of $X$, we can write

$$P_X(\dot{A}) = P_1^+(\dot{A}) - P_1^-(\dot{A}) + P_2^+(\dot{A}) - P_2^-(\dot{A}) + \cdots - P_{d-1}^-(\dot{A}) + P_d^+(\dot{A})$$
with the orthogonal projectors

\[ P_i^+(Z) = P_{\leq i-1} P_{\geq i+1}(Z) = \text{Ten}_i[(I_n \otimes P_{\leq i-1})Z^{i}]P_{\geq i+1}, \quad (1 \leq i \leq d), \]

\[ P_i^-(Z) = P_{\leq i} P_{\geq i+1}(Z) = \text{Ten}_i[P_{\leq i}Z^{i}]P_{\geq i+1}, \quad (1 \leq i \leq d - 1). \] (4.2) (4.3)

By standard theory (see, e.g., [7, II.5]), any splitting of this sum results in a first-order integrator, and composing it with the adjoint gives a second-order integrator, also known as the Strang splitting. Somewhat remarkably, we shall show that these split differential equations can be solved in closed form. Furthermore, if they are solved from left to right (or from right to left), the whole scheme can be implemented very efficiently.

4.1. Abstract formulation and closed-form solutions. Let \( t_1 - t_0 > 0 \) be the step size. One full step of the splitting integrator solves in consecutive order the following initial value problems over the time interval \([t_0, t_1] \):

\[ \begin{align*}
\dot{Y}_i^+ &= (+P_i^+(\dot{A})), & Y_i^+(t_0) &= Y_0, \\
\dot{Y}_i^- &= (-P_i^-(\dot{A})), & Y_i^+(t_0) &= Y_i^+(t_1), \\
& \vdots \\
\dot{Y}_i^+ &= (+P_d^+(\dot{A})), & Y_d^+(t_0) &= Y_d^+(t_1).
\end{align*} \]

Here, \( Y_0 = Y(t_0) \) is the initial value of (4.1) and \( Y_d^+(t_1) \) is the final approximation for \( Y(t_1) \). Observe that one full step consists of \( 2d - 1 \) substeps.

We remark that the projectors \( P_i^+, P_i^- \) depend on the current value of \( Y_i^+(t) \) or \( Y_i^-(t) \); hence, they are in general time-dependent. For notational convenience, we do not denote this dependence explicitly since the following result states we can actually take them to be time-independent as long as they are updated after every substep. In addition, it shows how these substeps can be solved in closed form.

**Theorem 4.1.** Let \( \Delta A = A(t_1) - A(t_0) \). For \( t_1 - t_0 > 0 \) sufficiently small, the initial value problems from above satisfy

\[ \begin{align*}
Y_i^+(t_1) &= Y_i^+(t_0) + P_i^+(\Delta A) \quad \text{and} \quad Y_i^-(t_1) = Y_i^-(t_0) - P_i^-(\Delta A),
\end{align*} \]

where \( P_i^+ \) and \( P_i^- \) are the projectors at \( Y_i^+(t_0) \) and \( Y_i^-(t_0) \), respectively.

In particular, if \( Y_i^+(t_0) \) has the recursive SVD

\[ [Y_i^+(t_0)]^{i} = Q_{\leq i}S_iQ_{\geq i+1}^T = (I_n \otimes Q_{\leq i-1})Q_i^TS_iQ_{i+1}^T, \]

with \( Q_{\leq 0} = Q_{\geq d+1} = 1 \), then

\[ [Y_i^+(t_1)]^{i} = (I_n \otimes Q_{\leq i-1}) \left\{ Q_i^TS_i + (I_n \otimes Q_{\leq i-1})[\Delta A]^{i}Q_{\geq i+1} \right\} Q_{i+1}^T. \]
Likewise, if \( Y_i^-(t_0) \) has the recursive SVD,
\[
[Y_i^-(t_0)]^{(i)} = Q_{\leq i} S_i Q_{\geq i+1}^T,
\]
then
\[
[Y_i^-(t_1)]^{(i)} = Q_{\leq i} \left\{ S_i - Q_{\leq i} [\Delta A]^{(i)} Q_{\geq i+1} \right\} Q_{\geq i+1}^T.
\]
These results are furthermore valid for any ordering of the initial value problems.

Proof. First, observe that each \( P_i^+ \) and \( P_i^- \) maps onto the current tangent space of \( \mathcal{M} \) and that \( Y_0 \in \mathcal{M} \). Hence, each \( Y_i^+(t) \) and \( Y_i^-(t) \) will stay on \( \mathcal{M} \) for \( t_1 - t_0 \) sufficiently small. We may therefore assume that \( Y_i^+(t) \) and \( Y_i^-(t) \) admit TT/MPS decompositions of equal TT/MPS rank for \( t \in [t_0, t_1] \).

By writing \( Y_i^+(t) \) in a time-dependent recursive SVD,
\[
[Y_i^+(t)]^{(i)} = (I \otimes Q_{\leq i-1}(t)) Q_{\geq i-1}(t) S_i(t) Q_{\geq i+1}^T(t),
\]
we see from (4.2) that
\[
[P_i^+(\dot{\hat{A}})]^{(i)} = (I \otimes Q_{\leq i-1}(t)) Q_{\geq i-1}(t)[\dot{\hat{A}}]^{(i)} Q_{\geq i+1}(t) Q_{\geq i+1}^T(t).
\]
Hence the differential equation \( \dot{Y}_i^+ = P_i^+(\dot{\hat{A}}) \) implies
\[
(I \otimes \dot{Q}_{\leq i-1}(t)) Q_{\geq i+1}^T(t) S_i(t) + (I \otimes Q_{\leq i-1}(t)) \frac{d}{dt} [Q_{\geq i+1}^T(t) S_i(t)] Q_{\geq i+1}^T(t)
+ (I \otimes Q_{\leq i-1}(t)) Q_{\geq i+1}^T(t) S_i(t) \dot{Q}_{\geq i+1}^T(t)
= (I \otimes Q_{\leq i-1}(t))(I \otimes Q_{\leq i-1}(t))[\dot{\hat{A}}]^{(i)} Q_{\geq i+1}(t) Q_{\geq i+1}^T(t).
\]
By choosing \( \dot{Q}_{\leq i-1}(t) = 0 \) and \( \dot{Q}_{\geq i+1}(t) = 0 \), the above identity is satisfied when
\[
\frac{d}{dt} [Q_{\geq i+1}^T(t) S_i(t)] = (I \otimes Q_{\leq i-1}(t))[\dot{\hat{A}}]^{(i)} Q_{\geq i+1}(t).
\]
(4.4)
Using the initial condition \( Y_i^+(0) \), the solution of these differential equations becomes
\[
Q_{\leq i-1}(t) = Q_{\leq i-1}(0), \quad Q_{\geq i+1}(t) = Q_{\geq i+1}(0),
Q_{\geq i+1}^T(t) S_i(t) = Q_{\geq i+1}^T(0) S_i(0) + (I \otimes Q_{\leq i-1}(0))[A(t) - A(0)]^{(i)} Q_{\geq i+1}(0),
\]
which proves the statement for \( [Y_i^+(\delta)]^{(i)} \). Now, writing
\[
[Y_i^+(\delta)]^{(i)} = (I \otimes Q_{\leq i-1}) Q_{\geq i+1}^T S_i(t) Q_{\geq i+1}^T + (I \otimes Q_{\leq i-1} Q_{\geq i+1}^T)[\Delta A]^{(i)} Q_{\geq i+1} Q_{\geq i+1}^T
= [Y_i^+(0)]^{(i)} + (I \otimes P_{\leq i-1})[\Delta A]^{(i)} P_{\geq i+1},
\]
we have also proven the first statement of the theorem.

Since the previous derivation is valid for any initial condition, it does not depend on a specific ordering of the initial value problems. The derivation for \( Y_i^-(t_1) \) is analogous to that of \( Y_i^+(t_1) \).

In a similar way as for the proof of Corollary 3.2 one can show that the projector \( P_i^+(Z) \) also satisfies
\[
P_i^+(Z) = \text{Ten}_{i-1} [P_{\leq i-1} Z^{(i-1)} (P_{\geq i+1} \otimes I_{n_i})], \quad (1 \leq i \leq d),
\]
(4.5)
This definition is useful when $Y^+_i(t_0)$ is given as (see (4.3))

$$[Y^+_i(t_0)]^{(i-1)} = Q_{\leq i-1} S_{i-1} Q_i^{\top} (Q_{\geq i+1} \otimes I_{n_i}).$$

In that case, we have

$$[Y^+_i(t_1)]^{(i-1)} = Q_{\leq i-1} \{S_{i-1} Q_i^{\top} + Q_i^{\top} [\Delta A]^{(i-1)} (Q_{\geq i+1} \otimes I_{n_i})\} (Q_{\geq i+1} \otimes I_{n_i}). \quad (4.6)$$

### 4.2. Efficient implementation as a sweeping algorithm.

Theorem [4.1] can be turned into an efficient scheme by updating the cores of the tensor $Y(t_0)$ from left to right. Our explanation will be high level, focusing only on pointing out which cores stay constant and which need to be updated throughout the sweep. A graphical depiction of the resulting procedure using tensor networks is visible in Fig. 4.1. More detailed implementation issues are deferred to [6.1].

**Preparation of $Y_0$.** Before solving the substeps, we prepare the starting value $Y_0$ as follows. Write $Y = Y_0$ for notational convenience and suppose

$$Y^{(1)}(t_0) = Y_{\leq 1}(t_0) Y_{\geq 2}(t_0).$$

By orthogonalization from the right we decompose $Y_{\geq 2}(t_0) = Q_{\geq 2}(t_0) R_2(t_0)$, so that we obtain the right-normalized factorization

$$Y^{(1)}(t_0) = K_1^c(t_0) Q_{\geq 2}(t_0)$$

with $K_1^c(t_0) = Y_{\leq 1}(t_0) R_2^T(t_0) \in \mathbb{R}^{n_1 \times r_1}$ the first core of $Y(t_0)$.

**Computation of $Y^+_1$.** Denote $Y = Y^+_1$. Since $Q_{\geq 2}(t_0) Q_{\geq 2}(t_0) = I_{r_1}$, we have that $P_{\geq 2}(t_0) = Q_{\geq 2}(t_0) Q_{\geq 2}^T(t_0)$. Applying Theorem [4.1] gives

$$Y^{(1)}(t_1) = K_1^c(t_1) Q_{\geq 2}(t_0),$$

with

$$K_1^c(t_1) = K_1^c(t_0) + (A^{(1)}(t_1) - A^{(1)}(t_0)) Q_{\geq 2}(t_0).$$

Observe that compared to $Y(t_0)$ only the first core $K_1(t_1)$ of $Y(t_1)$ is changed, while all the others (that is, those that make up $Q_{\geq 2}(t_0)$) stay constant. Hence, after computing the QR decomposition

$$K_1^c(t_1) = Q_1^c(t_1) R_1(t_1),$$

we obtain a recursive SVD for $Y(t_1) = Y^+_1(t_1)$,

$$Y^{(1)}(t_1) = Q_{\leq 1}(t_1) R_1(t_1) Q_{\geq 2}(t_0) \quad \text{with} \quad Q_{\leq 1}(t_1) = Q_1^c(t_1).$$

**Computation of $Y_i^−$ with $i = 1, \ldots, d - 1$.** The computation for $Y_1^−$ follows the same pattern as for arbitrary $Y_i^−$, so we explain it directly for $Y_i^−$.

We require that the initial value $Y_i^−(t_0) = Y_i^+(t_1)$ is available as a recursive SVD in node $i$. This is obviously true for $Y_1^+(t_1)$ and one can verify by induction that it is also true for $Y_i^+(t_1)$ with $i > 1$, whose computation is explained below. Denoting $Y = Y_i^−$, we have in particular

$$Y^{(i)}(t_0) = Q_{\leq 1}(t_1) R_1(t_1) Q_{\geq i+1}(t_0),$$
with $Q_{\geq i}^T(t_1)Q_{\leq i}(t_1) = I_i$, $Q_{\geq i+1}^T(t_0)Q_{\geq i+1}(t_0)$. This means we can directly apply Theorem 4.1 for the computation of $Y(t_1)$ and obtain

$$Y^{(i)}(t_1) = Q_{\leq i}(t_1)S_i(t_1)Q_{\geq i+1}^T(t_0),$$

where $S_i(t_1) \in \mathbb{R}^{r_i \times r_i}$ is given as

$$S_i(t_1) = R_i(t_1) - Q_{\leq i}^T(t_1)(A^{(i)}(t) - A^{(i)}(t_0))Q_{\geq i+1}(t_0).$$

Observe that we maintain a recursive SVD in $i$ for $Y_i^-(t_1)$ without having to having to orthogonalize the matrices $Q_{\leq i}(t_1)$ or $Q_{\geq i+1}(t_0)$.

**Computation of $Y_i^+$ with $i = 2, \ldots, d$.** In this case, the initial value $Y_i^+(t_0) = Y_{i-1}^-(t_1)$ is available as a recursive SVD in node $i - 1$. Denoting $Y = Y_i^+$, then it is easily verified by induction that

$$Y^{(i-1)}(t_0) = Q_{\leq i-1}(t_1)S_{i-1}(t_1)Q_{\geq i}^T(t_0),$$

with $Q_{\leq i-1}^T(t_1)Q_{\leq i-1}(t_1) = I_{r_{i-1}} = Q_{\leq i}^T(t_0)Q_{\geq i}(t_0)$. Recalling the relations (2.7) and (2.8), we can transform this $(i-1)$th unfolding into the $i$th unfolding,

$$Y^{(i)}(t_0) = (I_n \otimes Q_{\leq i-1}(t_1)) K^<_i(t_0) Q_{\geq i+1}^T(t_0)$$

where $K^<_i(t_0) = (I_n \otimes S_{i-1}(t_1))Q_{\leq i}(t_0)Q_{\geq i}(t_0)$. The result will be a recursive SVD of $Y^+(t_1) = Y(t_1)$ at node $i$.

$$Y^{(i)}(t_1) = (I_n \otimes Q_{\leq i-1}(t_1)) K^<_i(t_1) Q_{\geq i+1}^T(t_0),$$

where $K^<_i(t_1) \in \mathbb{R}^{(r_{i-1}n_i) \times r_i}$ is given by

$$K^<_i(t_1) = K^<_i(t_0) + (I_n \otimes Q_{\leq i-1}^T(t_1))(A^{(i)}(t_1) - A^{(i)}(t_0))Q_{\geq i+1}(t_0).$$

Since now only the $i$th core $K_i(t_1)$ of $Y(t_1)$ has changed, one QR decomposition

$$K^<_i(t_1) = Q^<_i(t_1)R_i(t_1),$$

suffices to obtain a recursive SVD of $Y^+_i(t_1) = Y(t_1)$ at node $i$.

**Next time step.** The final step $Y^+_d(t_1)$ will be an approximation to $Y(t_1)$ and consists of a left-orthogonal $Q_{\leq d}(t_1)$. If we now want to continue with the time stepper to approximate $Y(t_2)$ for $t_2 > t_1$, we need to apply the scheme again using $Y^+_d(t_1)$ as initial value. This requires a new orthogonalization procedure from right to left, since the initial value for the sweep has to be right normalized.

**4.3. Second-order scheme by a back-and-forth sweep.** In many cases, it is advisable to compose the scheme from above with its adjoint instead of only orthogonalizing and continuing with the next step. In particular, the Strang splitting consists of first computing the original splitting scheme on $t \in [t_0, t_{1/2}]$ with $t_{1/2} = (t_2 + t_1)/2$ and then applying the adjoint of this scheme on $t \in [t_{1/2}, t_2]$. The result will be a symmetric time stepper of order two; see, e.g., [2] II.5.
0) Prepared for $Y^+_i$

1) Compute contraction

3) Orthogonalize

5) Update core

6) Prepare for $Y^+_{i+1}$

Fig. 4.1. The two sweeping algorithms update the cores selectively throughout the time stepping computations. Visible for the forward sweep when computing $Y^+_i$ and $Y^-_i$.

For our splitting, the adjoint step is simply solving the split differential equations from right to left. Since Theorem 4.1 is independent on the order of the differential equations, we can again use its closed-form solutions to derive an efficient sweeping algorithm for this adjoint step. We briefly explain the first three steps and refer to Algorithm 1 for the full second-order scheme. Observe that this scheme can be seen as a full back-and-forth sweep.

Denote the final step of the forward sweep on $t \in [t_0, t_{1/2}]$ by $\tilde{Y} = Y^+_d(t_{1/2})$. It satisfies (recall that $t_1$ takes the role of $t_{1/2}$ in the derivations above)

$$\tilde{Y}^{(d)}(t_{1/2}) = (I_n \otimes Q_{\leq d-1}(t_{1/2}))K_d^{(d)}(t_{1/2}).$$
with
\[ K_d^<(t_{1/2}) = K_d^>(t_0) + (I_{n_d} \otimes Q^{-1}_{\leq d-1}(t_{1/2})) (A^{(d)}(t_{1/2}) - A^{(d)}(t_0)). \]

The first substep of the adjoint scheme consists of solving
\[ \hat{Y}_d^+ = +P_d^+(\hat{A}), \quad Y_d^+(t_{1/2}) = \hat{Y}, \]
on \( t \in [t_{1/2}, t] \). Denote \( Y = Y_d^+ \). We can directly apply Theorem 4.1 to obtain
\[ Y^{(d)}(t_1) = (I_{n_d} \otimes Q_{\leq d-1}(t_{1/2})) K_d^>(t_{1/2}) \]
with
\[ K_d^>(t_1) = K_d^>(t_{1/2}) + (I_{n_d} \otimes Q^{-1}_{\leq d-1}(t_{1/2})) (A^{(d)}(t_{1/2}) - A^{(d)}(t_0)) \]
\[ = K_d^>(t_0) + (I_{n_d} \otimes Q^{-1}_{\leq d-1}(t_{1/2})) (A^{(d)}(t_1) - A^{(d)}(t_0)). \]

Hence, the last substep of the forward sweep and the first of the backward sweep can be combined into one.

The second substep amounts to solving
\[ \hat{Y}_{d-1}^- = -P_{d-1}^-(\hat{A}), \quad Y_{d-1}^-(t_{1/2}) = Y_d^+(t_1). \]

Let \( Y = Y_{d-1}^- \). Then we can write the initial condition as
\[ Y^{(d-1)}(t_{1/2}) = Q_{\leq d-1}(t_{1/2}) K_d^>(t_1) \]
and using the QR decomposition \( K_d^>(t_1) = Q_d^>(t_1) R_{d-1} \) also as
\[ Y^{(d-1)}(t_{1/2}) = Q_{\leq d-1}(t_{1/2}) R_{d-1}^T(t_1) Q_d^T_{\geq d}(t_1), \]
where \( Q_{\geq d}(t_1) = Q_d^>(t_1) \). Applying Theorem 4.1 we obtain
\[ Y^{(d-1)}(t_1) = Q_{\leq d-1}(t_{1/2}) S_d^T_{d-1}(t_1) Q_d^T_{\geq d}(t_1), \]
where
\[ S_d^T_{d-1}(t_1) = R_{d-1}^T(t_1) - Q_{\leq d-1}(t_{1/2}) (A^{(d-1)}(t_1) - A^{(d-1)}(t_{1/2})) Q_{\geq d}(t_1). \]

For the third substep
\[ \hat{Y}_{d-1}^+ = +P_{d-1}^-(\hat{A}), \quad Y_{d-1}^+(t_{1/2}) = Y_{d-1}^-(t_1), \]
we denote \( Y = Y_{d-1}^+ \). In this case, unfold using (2.10) and (2.11) the computed quantity \( Y_{d-1} \) from above as
\[ Y^{(d-2)}(t_1) = Q_{\leq d-2}(t_{1/2}) K_{d-1}^>(t_{1/2}) (Q_d^T_{\geq d}(t_1) \otimes I_{n_{d-1}}), \]
with \( K_{d-1}^>(t_{1/2}) = Q_{d-1}^>(t_{1/2}) (S_{d-1}^T(t_1) \otimes I_{n_{d-1}}) \). From here on, all subsequent computations are straightforward if we use (4.6) to compute \( Y_{i}^+(t_1) \).
5. **Exactness property of integrator.** We show that the splitting integrator is exact when $A(t)$ is a tensor of constant TT/MPS rank $r$. This is similar to Theorem 4.1 in \cite{brandstetter2017} for the matrix case, except that in our case we require the rank of $A(t)$ to be exactly $r$ and not merely bounded by $r$. Note, however, that the positive singular values of unfoldings of $A(t)$ can be arbitrarily small.

**Theorem 5.1.** Suppose $A(t) \in M$ for $t \in [t_0, t_1]$. Then, for sufficiently small $t_1 - t_0 > 0$ the splitting integrators of orders one and two are exact when started from $Y_0 = A(t_0)$. For example, $Y_d^0(t_1) = A(t_1)$ for the first-order integrator.

The proof of this theorem follows trivially from the following lemma.

**Lemma 5.2.** Suppose $A(t) \in M$ for $t \in [t_0, t_1]$ with recursive SVDs

$$[A(t)]^{(i)} = Q_{\leq i}(t) S_i(t) Q_{\geq i+1}^T(t) \quad \text{for } i = 0, 1, \ldots, d.$$
Let $Y_0 = A(t_0)$, then for sufficiently small $t_1 - t_0 > 0$ the consecutive steps in the splitting integrator of $\mathcal{I}$ satisfy

$$Y_i^+(t_1) = P_{i+1}^{(0)} A(t_1) \quad \text{and} \quad Y_i^-(t_1) = P_i^{(1)} A(t_0) \quad \text{for } i = 1, 2, \ldots, d,$$

where

$$P_{i+1}^{(0)} Z = \text{Ten}_i(Z(t_0) Q_{i+1}(t_0) Q_i^\top(t_0)),$$

$$P_i^{(1)} Z = \text{Ten}_i(Q_{i+1}(t_1) Q_i^\top(t_1) Z(t_1)).$$

Before proving this lemma, we point out that the assumption of sufficiently small $t_1 - t_0$ is only because the matrices $Q_{i+1}(t_1) Q_i(t_0)$ need to be invertible. Since the full column-rank matrices $Q_i(t)$ and $Q_{i+1}(t)$ can be chosen continuous functions in $t$, this is always satisfied for $t_1 - t_0$ sufficiently small. It may however also hold for larger values of $t_1 - t_0$.

Proof. By induction on $i$ from left to right. Since $Y_i^+(t_0) = A(t_0)$, we can include the case for $Y_1^+(t_1)$ in our proof below for general $i$ by putting $Y_0^+(t_1) = Y_1^+(t_0)$ and $P_0^{(1)} = 1$.

Now, suppose true for $i > 1$, then $Y_i^+(t_0) = Y_{i-1}^+(t_1) = P_{i-1}^{(1)} A(t_0)$ which gives

$$[Y_i^+(t_0)]^{(i-1)} = Q_{i-1}(t_1) Q_i^\top(t_1) Q_{i-1}(t_0) S_{i-1}(t_0) Q_i^\top(t_0) = Q_{i-1}(t_1) S_{i-1}^+ Q_i^\top(t_0).$$

Observe that $Y_i^+(t_0) \in \mathcal{M}$ since $S_{i-1}^+ = Q_{i-1}^\top(t_1) Q_{i-1}(t_0) S_{i-1}(t_0)$ is full rank for $t_1 - t_0$ sufficiently small. Hence, from (2.7)–(2.8) we obtain

$$[Y_i^+(t_0)]^{(i)} = (I_n \otimes Q_{i-1}(t_1)) (I_n \otimes S_{i-1}^+) Q_i^\top(t_0) Q_i^\top(t_1).$$

Comparing to (3.1), we see that the projector onto the tangent space at $Y_i^+(t_0)$ equals

$$P_i^+ = P_{i+1}^{(1)} P_{i+1}^{(0)} = P_{i+1}^{(1)} P_{i+1}^{(0)} (1) \quad \text{for } i = 1, 2, \ldots, d. \quad \text{The previous identities give with Theorem 4.1 that}$$

$$Y_i^+(t_1) = Y_i^+(t_0) + P_i^+ A(t_1) - P_i^+ A(t_0)$$

$$= P_{i-1}^{(1)} A(t_0) + P_{i+1}^{(0)} P_{i-1}^{(1)} A(t_1) - P_{i-1}^{(1)} P_{i+1}^{(0)} A(t_0) = P_{i+1}^{(0)} A(t_1),$$

where we used $P_{i+1}^{(0)} A(t_0) = A(t_0)$ and $P_{i-1}^{(1)} A(t_1) = A(t_1)$.

Continuing with $Y_i^-(t_0) = Y_i^+(t_1) = P_i^{(0)} A(t_1)$, we have

$$[Y_i^-(t_0)]^{(i)} = Q_{i}(t_1) S_{i}(t_1) Q_{i+1}^\top(t_1) Q_{i+1}(t_0) Q_i^\top(t_0)$$

$$= Q_{i}(t_1) S_{i}^- Q_i^\top(t_1).$$

This is again a recursive SVD with full rank $S_i^- = S_i(t_1) Q_i^\top(t_1) Q_{i+1}(t_0)$. Comparing to (4.3), we have $P_i^- = P_{i+1}^{(1)} P_{i+1}^{(0)} = P_{i+1}^{(1)} P_{i}^{(0)}$ and Theorem 4.1 gives

$$Y_i^-(t_1) = Y_i^-(t_0) - P_i^- A(t_1) + P_i^- A(t_0)$$

$$= P_{i+1}^{(0)} A(t_1) - P_{i+1}^{(0)} P_{i}^{(1)} A(t_1) + P_{i}^{(1)} P_{i+1}^{(0)} A(t_0) = P_{i}^{(1)} A(t_0),$$

for $i = 1, 2, \ldots, d$. \quad \text{Q.E.D.}
where we used $P_{i}^{(i)} A(t_1) = A(t_1)$. This concludes the proof. \qed

Now, Theorem 5.1 is a simple corollary.

**Proof of Theorem 5.1.** For the forward sweep (that is, the first-order scheme), Lemma 5.2 immediately gives exactness since $Y_t^+(t_1) = P_{d+1}^{(0)}A(t_1) = A(t_1)$ with $Q_{d+1}(t_0) = 1$. The second-order scheme composes this forward sweep with a backward sweep involving the same substeps. It is not difficult to prove the analogous version of Lemma 5.2 for such a backward ordering such that we establish exactness for the second-order scheme too. \qed

6. **Numerical implementation and experiments.** We consider two numerical experiments. First, we use the splitting integrator for the integration of a time-dependent molecular Schrödinger equation with model potential. In the second experiment, we use one step of the splitting integrator as a retraction on the manifold of TT/MPS tensors and perform a Newton-Schultz iteration for approximate matrix inversion.

6.1. **Implementation details.** As explained in 4.2-4.3, the integrator updates the cores $K_i$ and matrices $S_i$ in a forward, and possibly, backward ordering. Except for the (relatively cheap) orthogonalizations of the cores, the most computationally intensive part of the algorithm is computing these updates. For example, in the forward sweep, we need to compute the contractions (see Fig. 4.1)

\[
\Delta_i^+ = (I \otimes Q_{i-1}^+(t_1)) [A(t_1) - A(t_0)]^{[i]} Q_{i+1}(t_0),
\]

\[
\Delta_i^- = Q_i^+(t_1) [A(t_1) - A(t_0)]^{[i]} Q_{i+1}(t_0).
\]

It is highly recommended to avoid constructing the matrices $Q_{\leq i}$ and $Q_{\geq i}$ explicitly when computing $\Delta_i^+$, $\Delta_i^-$ and instead exploit their TT/MPS structure. How this can be done, depends mostly on the structure of the increments $A(t_1) - A(t_0)$. In particular, the contractions are computed inexpensively if $A(t)$ is itself a linear combination of TT/MPS tensors, possibly of different rank than $Y_t$, and a sparse tensor.

The computation of $K_i$ and $S_i$ changes when the tensor $A(t)$ is not given explicitly, but determined as the solution of a tensor differential equation

\[
\dot{A}(t) = F(t, A(t)).
\]

In case of a forward sweep, $Y_i^+(t_1)$ is obtained as the evaluation at $t = t_1$ of

\[
Y_i^+(t) = (I \otimes Q_{i-1}^+(t_1)) K_i^-(t) Q_{i+1}(t_0),
\]

where $K_i^-(t) = Q_i^-(t) S_i(t)$ satisfies 4.4. Hence, for $\dot{A}(t) = F(t, Y_t(t))$, we obtain

\[
\dot{K}_i^- = (I \otimes Q_{i-1}^+(t_1)) [F(t, Y_i^+(t))]^{[i]} Q_{i+1}(t_0).
\]

In an analogous way, the result of the next substep $Y_i^-(t_1)$ is obtained from

\[
Y_i^-(t) = Q_{\leq i}(t_1) S_i(t) Q_{i+1}(t_0),
\]

\[
\dot{S}_i = -Q_{\leq i}^+(t_1)) [F(t, Y_i^-(t))]^{[i]} Q_{i+1}(t_0).
\]

These differential equations can be solved numerically by a Runge-Kutta method (of order at least 2 for the second-order splitting integrator). In the important particular case of an autonomous linear ODE

\[
\dot{A}(t) = F(t, A(t)) = L(A(t)), \quad \text{with linear } L: \mathbb{R}^{n_1 \times \cdots \times n_d} \to \mathbb{R}^{n_1 \times \cdots \times n_d},
\]
the above differential equations are constant-coefficient linear differential equations for $K_i$ and $S_i$, respectively, which can be solved efficiently with a few iterations of a Krylov subspace method for computing the action of the operator exponential \[8, 26, 9\].

### 6.2. Quantum dynamics in a model potential.
Quantum molecular dynamics is one of the promising applications of the split projector integrator. As a test problem, we use the same setup as considered in [22]: the time-dependent Schrödinger equation with Henon–Heiles potential modeling a coupled oscillator,

\[
\frac{d\psi}{dt} = iH\psi, \quad \psi(0) = \psi_0, \tag{6.1}
\]

where the Hamiltonian operator $H$ has the form

\[
H(q_1, \ldots, q_f) = -\frac{1}{2} \Delta + \frac{1}{2} \sum_{k=1}^f q_k^2 + \lambda \sum_{k=1}^{f-1} \left( q_k^2 q_{k+1} - \frac{1}{3} q_{k+1}^3 \right) \tag{6.2}
\]

with $\lambda = 0.111803$. As an initial condition $\psi_0$, we choose a product of shifted Gaussians,

\[
\psi_0 = \prod_{i=1}^f \exp \left( -\frac{(q_i - 2)^2}{2} \right).
\]

The correct discretization of such problems is delicate. A standard approach is to use a Discrete Variable Representation (DVR), specifically, the Sine-DVR scheme from [3]. In addition, since the problem is defined over the whole space, appropriate boundary conditions are required. We use complex absorbing potentials (CAP) of the form (see, for example, [20])

\[
W(q) = i\eta \sum_{i=1}^f \left( (q_i - q_i^{(r)}) z_+ + (q_i - q_i^{(l)}) z_- \right),
\]

where

\[
z_+ = \begin{cases} z, & \text{if } z \geq 0, \\ 0, & \text{otherwise}, \end{cases} \quad \text{and} \quad z_- = \begin{cases} z, & \text{if } z \leq 0, \\ 0, & \text{otherwise}. \end{cases}
\]

The parameters $q_i^{(r)}$ and $q_i^{(l)}$ specify the effective boundary of the domain. CAP reduces the reflection from the boundary back to the domain, but the system is no longer conservative. For the Henon–Heiles example from above we have chosen

\[
\eta = -1, \quad q_i^{(l)} = -6, \quad q_i^{(r)} = 6, \quad b_r = b_l = 3.
\]

We compute the dynamics using the second-order splitting integrator where the (linear) local problems for $K_i, S_i$ are integrated using the Expokit package [26] with a relative accuracy of $10^{-8}$.

In order to evaluate the accuracy and efficiency of our proposed split integrator, we performed a preliminary comparison with the multi-configuration time-dependent
Hartree (MCTDH) package [29]. The MCTDH method [20] is the de-facto standard for doing high-dimensional quantum molecular dynamics simulations. For the detailed description of MCTDH, we refer to [20, 21, 2, 19].

As numerical experiment, we run MCTDH for the 10-dimensional Henon–Heiles problem from above with mode-folding. This can be considered as a first step of the hierarchical Tucker format (in this context called the multilayer MCTDH decomposition) with 32 basis functions in each mode, and the resulting function was approximated by a 5-dimensional tensor with mode sizes equal to 18. The final time was $T = 60$. Our split integrator solved the same Henon–Heiles problem but now using the second-order split integrator with a fixed time step $h = 0.01$. Except that we use the TT/MPS manifold for our scheme instead of a Tucker-type manifold in MCDTH, all other computational parameters are the same.

In Fig. 6.1 we see the vibrational spectra of molecules which is obtained as follows. After the dynamical low-rank approximation $\hat{\psi}(t)$ is computed, we evaluate the autocorrelation function $a(t) = \langle \psi(t), \psi(0) \rangle$, and compute its Fourier transform $\hat{a}(\xi)$. The absolute value of $\hat{a}(\xi)$ gives the information about the energy spectrum of the operator. If the dynamics are approximated sufficiently accurately, the function $\hat{a}(\xi)$ is approximated as a sum of delta functions located at the eigenvalues of $H$. This method can be considered as a method to approximate many eigenvalues of $H$ by using only one solution of the dynamical problem, which is not typical to standard numerical analysis, but often used in chemistry.

We see in Fig. 6.1 that the computed spectra are very similar, but the MCTDH computation took 54 354 seconds, whereas the split integrator scheme took only 4 425 seconds. A detailed comparison of the splitting scheme and MCTDH for quantum molecular dynamics will be presented elsewhere which will include different benchmark problems and a comparison with the multilayer version of the MCTDH.
6.3. Approximate matrix inversion. Optimization on low-rank tensor manifolds is another promising application of the split integrator scheme and can be rather easily incorporated. Consider some iterative process of the form

$$Y_{k+1} = Y_k + \Delta_k \quad k = 0, \ldots$$

(6.3)

where $\Delta_k$ is the update. In order to obtain approximations $Z_k \in \mathcal{M}$ of $Y_k$ in the TT/MPS format, one typically retracts the new iterate back to $\mathcal{M}$,

$$Z_{k+1} = P_r(Z_k + \Delta_k),$$

with $P_r : \mathbb{R}^{n_1 \times \cdots \times n_d} \to \mathcal{M}$ a retraction; see [1]. A widely used choice for $P_r$ is the quasi-optimal projection computed by TT-SVD [24]. Instead, we propose the cheaper alternative of one step of Algorithm 1 with $A(t_1) - A(t_0) = \Delta_k$ as $P_r$. In practice, the intermediate quantities in Algorithm 1 have to be computed without forming $\Delta_k$ explicitly. This can be done, for example, when $\Delta_k$ is a TT/MPS tensor of low-rank as explained in §6.1.

An important example of (6.3) is the Newton–Schultz iteration for the approximate matrix inversion (see, e.g., [5]),

$$Y_{k+1} = 2Y_k - Y_k AY_k, \quad k = 0, \ldots$$

(6.4)

It is well-known that iteration (6.4) converges quadratically provided that $\rho(I - AY_0) \leq 1$, where $\rho(\cdot)$ is the spectral radius of the matrix. Matrix $A$ is supposed to have low TT/MPS rank when seen as a tensor. This typically arises from a discretization of a high-dimensional operator on a tensor grid. In our numerical experiments we have taken the $M$-dimensional Laplace operator with Dirichlet boundary conditions, discretized on a uniform grid with $2^d$ points in each mode.

As a low-rank format, we used the quantized TT-format (QTT) [23, 12] which coincides with a $Md$-dimensional TT/MPS format with all dimensions $n_i = 2$. It is known [11] that in this format the matrix $A$ is represented with QTT-ranks bounded by 4. Since $A$ is symmetric positive definite, as an initial guess we choose $Y_0 = \alpha I$ with a sufficiently small $\alpha$. The split integrator is applied with $\Delta_k = Y_k - Y_k AY_k$. It requires a certain amount of technical work to implement all the operations involved in the QTT format, but the final complexity is linear in the dimension of the tensor (but of course, has high polynomial complexity with respect to the rank). To put the solution onto the right manifold we artificially add a zero tensor to the initial guess, which has rank 1, and formally apply the split integrator.

As first numerical result, we compare the split projector scheme to the standard approach where after each step of the Newton-Schultz iteration we project onto a manifold of tensors with bounded TT/MPS ranks $r$ using the TT-SVD,

$$Y_{k+1} = P_r(2Y_k - Y_k AY_k).$$

The parameters are set as $M = 2$, $d = 7$, $r = 20$, $\alpha = 10^{-2}$. The convergence of the relative residual $\|AY_k - I\| / \|AY_0 - I\|$ in the Frobenius norm for the two methods is presented in Fig. [6.2]. The split projector has slightly better accuracy and, more importantly, is significantly faster.

During the numerical experiments we observed that the residual always decreases until the point when the manifold is insufficient to hold a good approximation to an inverse, and then it either stabilizes or diverges. The exact explanation of this
Fig. 6.2. Convergence of split projector method and the SVD-based projection method for $D = 2$, $d = 7$, $\alpha = 10^{-2}$, $r = 20$.

Fig. 6.3. The relative residual vs. iteration number for the approximate inversion using TT/MPS rank $r$ of the $M$-dimensional Laplace operator on a uniform grid with $2^7 = 128$ points in each dimension. Fixed starting guess $Y_0 = \alpha I$ with $\alpha = 10^{-6}$.

behavior is out of the scope of the current paper but could probably be solved using a proper line-search on $M$ as in [1]. Fig. 6.3 shows the convergence behavior for different $M$ and $r$, with $d$ and $\alpha$ fixed. Fig. 6.4 shows the convergence behavior with respect to different $\alpha$ and $d$. Finally, Fig. 6.5 shows that the code has good scaling with $d$ and $M$.

7. Conclusion. We have presented and studied a robust and computationally efficient integrator for updating tensors in the tensor train or matrix product state format and for approximately solving tensor differential equations with the approximations retaining the data-sparse tensor train format. Quantum dynamics and tensor optimization appear as promising application areas.

It appears possible to extend this approach to the manifold of hierarchical Tucker tensors of fixed rank [27] and its dynamical approximation [18]. This will be reported elsewhere.

Acknowledgement. We thank Jutho Haegeman and Frank Verstraete for helpful discussions regarding the split integrator, and Hans-Dieter Meyer for explaining the basic concepts behind quantum molecular dynamics simulations and for his help with the MCTDH package.
