ABSTRACT

In this work we analyze the physical properties of a sample of 56 spectroscopically selected star-forming (SF) Ly α emitting galaxies at $2.0 \lesssim z \lesssim 3.5$ using both a spectral energy distribution (SED) fitting procedure from rest-frame UV to mid-IR and direct $160\mu\text{m}$ observations taken with the Photodetector Array Camera & Spectrometer (PACS) instrument onboard *Herschel Space Observatory*. We define LAEs as those Ly α emitting galaxies whose rest-frame Ly α equivalent widths (Ly α EW_{rest-frame}) are above 20\AA , the typical threshold in narrow-band searches. Ly α emitting galaxies with Ly α EW_{rest-frame} are called non-LAEs. As a result of an individual SED fitting for each object, we find that the studied sample of LAEs contains galaxies with ages mostly below 100Myr and a wide variety of dust attenuations, SFRs, and stellar masses. The heterogeneity in the physical properties is also seen in the morphology, ranging from bulge-like galaxies to highly clumpy systems. In this way, we find that LAEs at $2.0 \lesssim z \lesssim 3.5$ are very diverse, and do not have a bimodal nature, as suggested in previous works. Furthermore, the main difference between LAEs and non-LAEs is their dust attenuation, because LAEs are not as dusty as non-LAEs. On the FIR side, four galaxies of the sample (two LAEs and two non-LAEs) have PACS-FIR counterparts. Their total IR luminosity place all of them in the ULIRG regime and are all dusty objects, with $A_{1200} \gtrsim 4\text{mag}$. This is an indication from direct FIR measurements that dust and Ly α emission are not mutually exclusive. This population of red and dusty LAEs is not seen at $z \sim 0.3$, suggesting an evolution with redshift of the IR nature of galaxies selected via their Ly α emission.

Key words. cosmology: observations – galaxies: stellar populations, morphology, infrared.

1. Introduction

Over the past years, a large number of galaxies have been found at different redshifts, from the local universe up to $z \sim 7$ and even beyond. One of the most successful selection methods for searching for high-redshift galaxies is the narrow-band technique. It employs a combination of narrow and broad band filters to isolate the Ly α emission in the spectrum of a galaxy and to constrain its nearby continuum, respectively. This method segregates galaxies with a Ly α emission whose rest-frame Ly α equivalent width (Ly α EW_{rest-frame}) is typically above 20\AA . They are called Ly α emitters (LAEs).

Many efforts have been aimed at looking for LAEs in a wide range of redshifts (Deharveng et al., 2008; Cowie et al., 2010, 2011; Bongiovanni et al., 2010; Guaita et al., 2010; Cowie & Hu, 1998; Gronwall et al., 2007; Gawiser et al., 2006; Ouchi et al., 2008; Rhoads et al., 2000; Shioya et al., 2009; Murayama et al., 2007; Ouchi et al., 2010). Physical properties of LAEs have been mostly analyzed by fitting their observed spectral energy distribution (SED) with Bruzual & Charlot (2003, hereafter BC03) templates. This allows the determination of their dust attenuation, star-formation rate (SFR), age or stellar mass (Finkelstein et al., 2008, 2009a,b; Nilsson et al., 2007, 2009, 2011; Cowie et al., 2011; Ono et al., 2010; Lai et al., 2008; Pirzkal et al., 2007; Gawiser et al., 2006, 2007).

BC03 templates do not take the dust emission in the FIR into account and, even if they did, the lack of FIR information for LAEs, mainly at $z \gtrsim 2$, would produce important physical parameters, such as dust attenuation and SFR, suffering from large

uncertainties. In Oteo et al. (2011a,b) we look for mid-IR/FIR counterparts of a sample of LAEs at $z \sim 0.3$ by using PACS-100 μm , PACS-160 μm , and MIPS-24 μm data, finding that a high percentage of them ($\sim 75\%$) are detected at those wavelengths. These detections enable us to determine their IR nature, dust attenuation, and SFR without the intrinsic uncertainties of SED fitting. As a result, we find that LAEs at $z \sim 0.3$ are among the least dusty galaxies at that redshift and the majority have total IR luminosities below $10^{11} L_{\odot}$.

The $2 \lesssim z \lesssim 3.5$ range (1.7 to 3.2 Gyr after the Big Bang) is where the SFR density of the Universe is at a maximum (Hogg et al., 1998; Hopkins, 2004; Hopkins & Beacom, 2006; Pérez-González et al., 2005; Le Floc’h et al., 2005), and, with respect to LAEs, it has only started to be studied recently. Nilsson et al. (2009) demonstrate that there is a significant evolution in the physical properties of LAEs between $z \sim 3.0$ and $z \sim 2.3$, with a spread in their SEDs which is greater at $z \sim 2.3$ than at $z \sim 3.0$. This indicates that LAEs at $z \sim 2.3$ are more massive, older, and/or dustier than those at higher redshifts. Nilsson et al. (2011) find that both the dust attenuation and stellar mass of LAEs at $z \sim 2.3$ are high, mainly spanning $A_V = 0.0\text{--}2.5$ mag and $\log(M_*/M_{\odot}) = 8.5\text{--}11.0$, respectively. They also find that physical properties of LAEs at that redshift are very diverse. Guaita et al. (2011) obtain robust determinations of mass and dust attenuation, $\log(M_*/M_{\odot}) = 8.6[8.4\text{--}9.1]$ and $E(B-V) = 0.22[0.00\text{--}0.31]$, for LAEs at $z \sim 2.1$. Furthermore, comparing with a sample of LAEs at $z \sim 3.1$, they find that LAEs at $z \sim 2.1$ tend to be dustier and show higher instantaneous SFR than those at $z \sim 3.1$, and the properties are also diverse. Bond et al. (2011) claim between $z \sim 3.1$ and ~ 2.1 for an evolution of the morphological properties of LAEs, with the median half-light radii rising with decreasing redshift. They also report that LAEs at $z \sim 2.1$ are bigger for galaxies with higher stellar mass, star formation rate, and dust obscuration. Therefore, $2.0 \lesssim z \lesssim 3.0$ is an interesting redshift range for several reasons: 1) large samples of LAEs are being collected, 2) in this redshift range, LAEs tend to have bright observable fluxes, which allows a multiwavelength coverage with a higher signal-to-noise ratio than at higher redshifts, 3) it is a redshift range where the physical properties of LAEs seem to be changing significantly and become very diverse, while this has not been clearly reported at higher redshifts.

In this work, we focus on a sample of spectroscopically selected Ly α emitting galaxies at $2 \lesssim z \lesssim 3.5$. The spectroscopic selection segregates galaxies with Ly α $EW_{rest-frame}$ either above or below 20 \AA , the typical threshold in narrow-band searches. To place our contribution in a common base with narrow-band selected galaxies, we distinguish the following throughout the work: *LAEs*: Ly α emitting galaxies with Ly α $EW_{rest-frame} > 20 \text{ \AA}$; *non-LAEs*: Ly α emitting galaxies with Ly α $EW_{rest-frame} < 20 \text{ \AA}$. The main objective of this work is to give a first glimpse at the FIR properties of LAEs at $2.0 \lesssim z \lesssim 3.5$ by using deep FIR data coming from *Herschel*-PACS observations (Poglitsch et al., 2010; Pilbratt et al., 2010). Furthermore, with the aim of better understanding this population in that redshift range, we also study their physical properties by employing a SED fitting procedure with BC03 templates. This allows the comparison between SED fitting and IR-based results.

This paper is divided in two main parts. First, in Sections 2, 3, 4, and 5 we describe the optical to mid-IR data used in this work, perform SED fittings with BC03 templates, and carry out a morphological analysis. Then, in Section 6, we focus on the FIR side of their SED, studying total IR luminosities, IR nature,

Fig. 1. Redshift distribution of the sources in the final sample. We study objects at $2 \lesssim z \lesssim 3.5$.

total SFR, and dust attenuation for the FIR-detected galaxies. Section 7 gives the conclusions of this work.

Throughout this paper we assume a flat universe with $(\Omega_m, \Omega_{\Lambda}, h_0) = (0.3, 0.7, 0.7)$. All magnitudes are listed in the AB system (Oke & Gunn, 1983).

2. Optical data and object selection

The sample used in this work was selected from the final data release of the VIMOS spectroscopic campaign in the GOODS-South field (Popesso et al., 2009; Balestra et al., 2010). VIMOS spectra have a quality flag assigned as follows: A (secure classification), B (likely classification), and C (tentative classification). From all the spectra in the survey, we only selected those galaxies that exhibit a Ly α emission in their spectrum and which are flagged as A or B. This yields a sample of 144 objects. The wavelength coverage of the spectra implies that the LAEs are distributed within $2.0 \lesssim z \lesssim 3.5$. Throughout this work, the objects are named as in Popesso et al. (2009).

With the aim of carrying out SED fittings for the studied galaxies, we used the MUSIC multiwavelength photometric catalog (from 0.3 to 24.0 μm) of a large and deep area in the GOODS-South Field. Its first version was made by Grazian et al. (2006), and a subsequent update was elaborated by Santini et al. (2009). The former uses F435W, F606W, F775W, and F850LP ACS images, JHKs ISAAC data, mid-IR data provided by IRAC instrument (3.6, 4.5, 5.8, and 8.0 μm), and publicly available U-band data from WFI and VIMOS. The z-band of ACS GOODS frames and Ks of VLT images were used to select objects in the field, yielding a unique, autoconsistent catalog. The details of the catalogs (object detections, PSF-matchings, limiting magnitudes, etc.) can be found in Grazian et al. (2006). The second version includes objects selected from the IRAC-4.5 μm image and, therefore, sources detected in that wavelength but very faint or undetected in K_s band. MIPS-24 μm photometry was also included, although it will not be considered in the SED fittings (see Section 3). Owing to these improvements, we adopted the second version of the photometric catalog.

Fig. 2. Histogram of the magnitudes in the V band of the final sample of 56 LAEs. The values appearing here are similar to those in the UV-bright sample of Guaita et al. (2011).

To build our final sample of *Ly α* emitting galaxies, we matched the coordinates of 144 spectra with the MUSIC catalog, resulting in a total of 70 objects. The loss of 50% of the sources is explained by the area covered by the VIMOS spectroscopic observations being larger than the GOODS-MUSIC footprint. From that common sample, we visually inspected each spectrum, ruling out objects with no clear *Ly α* emission or with AGN ionization lines in their spectra. We finally ended with a clean sample of 56 *Ly α* emitting galaxies whose optical spectra suggest that they have a star-forming (SF) nature. Figure 1 shows the redshift distribution of the objects in the final sample. It can be seen that most of them are at $2.0 \lesssim z \lesssim 2.7$, although we also have a significant number of sources at $z \gtrsim 3$. Figure 2 shows the distribution of the observed V-band magnitude of the studied galaxies. Most of them are brighter than 25.5 mag in that band, which is comparable to the brightness of the UV-bright subsample defined in Guaita et al. (2011). The main advantage of working with a continuum-bright sample is that it is possible to carry out individual SED fitting for each galaxy, avoiding the uncertainties of stacking (Nilsson et al., 2011).

3. SED fitting method

We performed SED fittings with BC03 templates for the sample of 56 galaxies by using the Zurich Extragalactic Bayesian Redshift Analyzer (ZEBRA, Feldmann et al., 2006). In its maximum-likelihood mode, ZEBRA employs a χ^2 minimization algorithm over the templates to find the one that fits the observed SED of each object best. In this process, we excluded the MIPS-24 μ m measurements, since the fluxes in this band have a significant contribution of warm dust and PAH molecules emission, which are not taken into account in the BC03 templates. We employed GALAXEV, which is provided by BC03, to build a large sample of templates. In this process we adopted a Salpeter (1955) initial mass function, distributing stars from 0.1 to 100 M_{\odot} . This IMF has mostly been used in previous works in the studied redshift range (Guaita et al., 2011; Nilsson et al.,

2011; Lai et al., 2008; Ono et al., 2010; Gawiser et al., 2006, 2007). Since metallicities do not significantly modify the shape of the SEDs of galaxies, we adopted $Z=0.4Z_{\odot}$. Different authors employ different values: Lai et al. (2008) and Guaita et al. (2011) consider the solar metallicity, whereas Ono et al. (2010) utilize a value of $0.2Z_{\odot}$. To check the validity of our choice, we ran ZEBRA with BC03 templates associated to different metallicities and we find similar results for the other parameters, within the uncertainties. This, at the same time, is an indication that metallicity is difficult to determine accurately with SED fitting. For the SFR, we use models with temporally constant values, as in many previous works (Gawiser et al., 2006; Lai et al., 2008; Ono et al., 2010; Guaita et al., 2011; Kornei et al., 2010). In this case, the SFR can be obtained from the rest-frame UV fluxes once the templates are normalized to the observed photometry and employing the Kennicutt (1998) calibration between SFR and the UV luminosity. We also tried to use exponentially decreasing SFR, but the differences between the results for age and dust attenuation were not significant. Ono et al. (2010) also compare the results obtained with constant and varying SFR and find similar results in both cases, which indicates that the history of the star formation in a galaxy is hard to constrain with SED-fitting methods. Furthermore, adopting an exponentially varying SFR would add a new degree of freedom in the process, the star-formation time scale, introducing more uncertainties in the determination of the other parameters.

The ages considered here span from 1 Myr to 3.4 Gyr, the age of the universe at the minimum redshift of the sample, $z \sim 2.0$. Dust attenuation is included via the Calzetti et al. (2000) law with values of the color excess in the stellar continuum, $E(B-V)_s$, ranging from 0 to 0.7 in steps of 0.05. We also include intergalactic medium absorption adopting the prescription of Madau (1995). Stellar masses are obtained from SFR and age, according to the assumed temporal variation of the SFR. Regarding the uncertainties in the fitted values, ZEBRA provides a parameter related to the probability that one template truly represents the observed photometry of a given source. In the SED fitting of each galaxy, we select all the templates whose associated probability is above 68% and consider the uncertainty of each parameter as the average of the values associated to that parameter on the selected templates with more than 60% of probability.

4. Stellar populations

Figure 3 and Table A.1 show the results of the SED fitting for the studied galaxies. The dust attenuation of the studied LAEs, parametrized by the color excess in the stellar continuum $E(B-V)_s$, ranges from 0 to 0.3, with a median value of 0.15. The uncertainties in dust attenuation have a lower limit equal to the sampling of this parameter in the templates, that is, $\Delta E(B-V)_s \sim 0.05$, and are also affected by the well-known degeneracy between age, dust attenuation, and metallicity of the SED-fitting methods. Despite the uncertainties, the values obtained here are distributed within approximately the same interval as in Guaita et al. (2011) for the UV-bright sample, although their median value, $E(B-V) \sim 0.32$, is higher than that found in the present work.

Regarding age, the studied LAEs are young galaxies, most of them having ages below 100 Myr. However, there are some LAEs, $\sim 20\%$, whose SEDs are compatible with older populations, above 300 Myr. Although the threshold age in the generation of the templates was set to the age of the universe at $z \sim 2$, there is no violation of the age of the universe for galaxies at

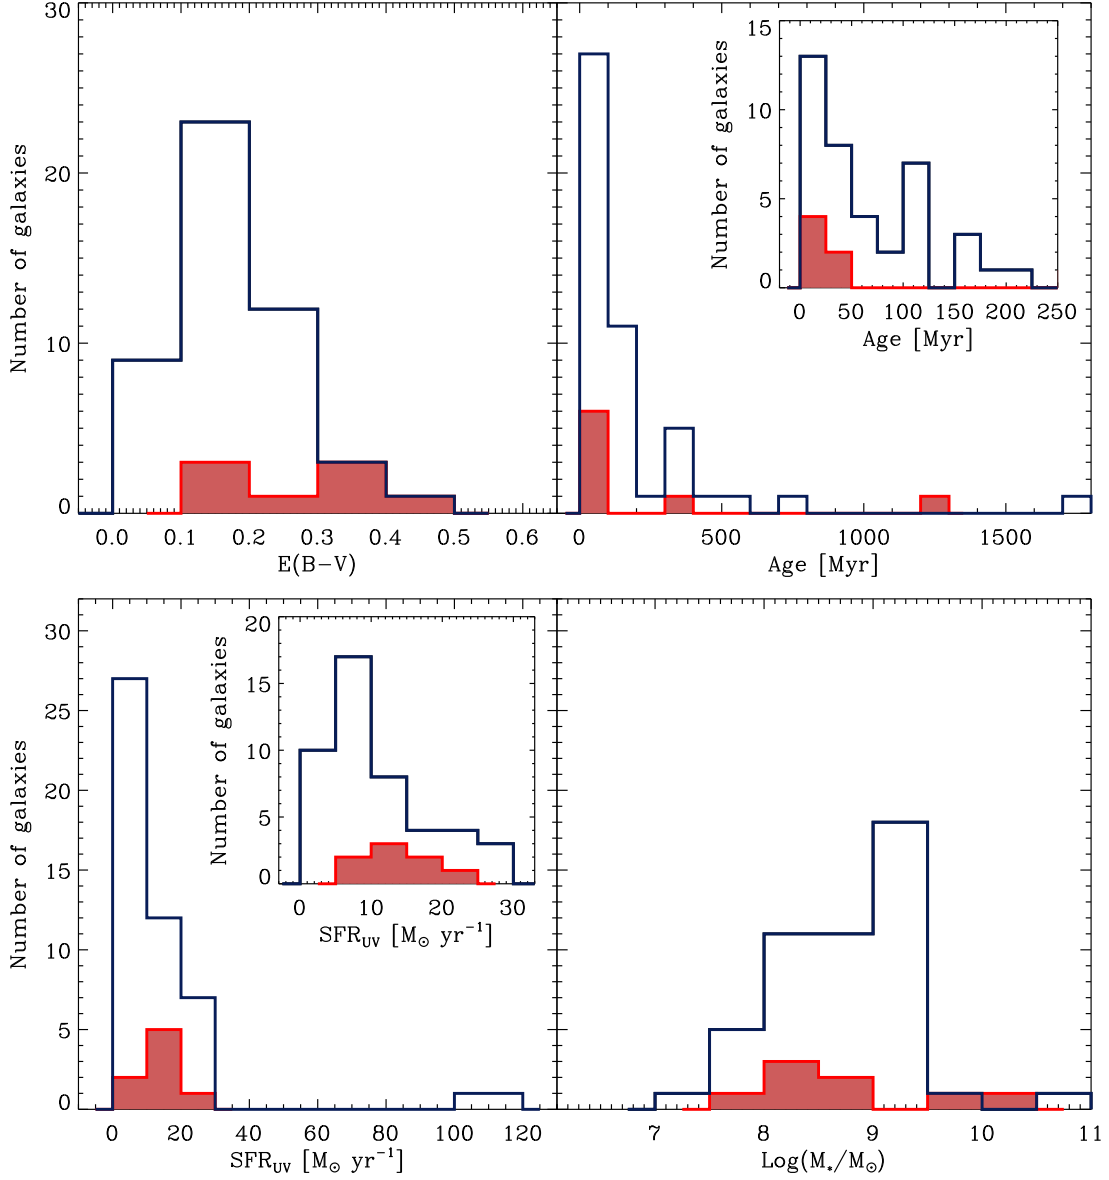

Fig. 3. Distribution of the physical properties for the sample of 56 LAEs. Blue and red-shaded histograms represent LAEs and non-LAEs, respectively. Inset plots are more detailed representations of the zones of the histograms where most objects are located.

higher redshifts. The uncertainties in age are typically below the 20%, which hints towards robust age estimations.

Intense rest-frame optical emission lines, such [OII], [OIII] or $H\alpha$, could have a strong effect on the observed broadband photometry of a galaxy. At $z \sim 0.3$, Cowie et al. (2011) employed their rest-frame optical spectroscopic observations of their LAEs to analyze the influence of rest-frame optical emission lines on the derived parameters in a SED fitting procedure. As a result, it was found that not subtracting those lines overestimates of the ages of the LAEs in their sample. In our work, given that we do not have spectral information about the [OII], [OIII], or $H\alpha$ emission for the studied galaxies, we can not correct for this effect, and, so the ages obtained here should be considered as an upper limit of the real values.

Since the studied LAEs have a bright UV continuum, their dust-uncorrected SFRs, $SFR_{UV,uncorrected}$, are high, ranging from about 2 to $100 M_{\odot} \text{ yr}^{-1}$, with a median value of $SFR_{UV,uncorrected} \sim 10 M_{\odot} \text{ yr}^{-1}$. These values are slightly higher than those reported at lower redshifts. In Oteo et al. (2011b)

we studied the $SFR_{UV,uncorrected}$ for LAEs at $z \sim 0.3$, finding that most of them have $SFR_{UV,uncorrected}$ below $5 M_{\odot} \text{ yr}^{-1}$. In the present work we do not see such low values because of the UV-brightness of the studied LAEs. However, the high values found at $2.0 \lesssim z \lesssim 3.5$ are not seen at $z \sim 0.3$. This could suggest that the upper limit of the $SFR_{UV,uncorrected}$ in LAEs is increasing from 0.3 to $z \gtrsim 2$, or similarly, that there is an evolution in the upper limit of the UV luminosity, L_{UV} . The surveyed comoving volume in Oteo et al. (2011b) and in the present work are similar given that the GALEX observations used in the former cover a much larger area of the sky than those used in the present work because the larger surveyed area at $z \sim 0.3$ makes up for the difference in redshifts. Cowie et al. (2011) report a strong evolution in the Ly α luminosity function of LAEs between $z \sim 0.3$ and ~ 1.0 , which could be related to the evolution in the upper limit of L_{UV} reported above. This suggests that there is a noticeable change in the UV properties of galaxies selected via their Ly α emission from $z \sim 0.3$ to $z \gtrsim 2.0$.

Fig. 4. Color-color diagram containing the locus of LBGs according to Pentericci et al. (2010). Filled and open dots represent LAEs and non-LAEs, respectively. Orange and blue dots represent galaxies at $z > 2.75$ and $z < 2.75$, respectively. Red dots are PACS-detected galaxies and shaded zone is the area where LBGs are located. For clarity, the galaxies with a $U-V$ color greater than 5.5 are assigned $U-V=5.5$.

The stellar mass of the studied LAEs spans within $7.0 \lesssim \text{Log}(M_*/M_\odot) \lesssim 9.5$. More than 70% of the studied Ly α emitting galaxies are detected in IRAC- $3.6\mu\text{m}$ under a similar limiting luminosity to the one in Lai et al. (2008). In this way, we are working with a sample of IRAC-bright sources, and they should be among the most massive LAEs in the studied redshift range. The range of stellar masses obtained here is compatible with the results of Guaita et al. (2011) for the UV-bright sample and with those at $z \sim 3.0$ of Lai et al. (2008) and Gawiser et al. (2006, 2007) for both IRAC-detected and IRAC-undetected stacked samples.

After inspecting the individual SED fittings we conclude that there is a wide range of shapes, from almost-dust free cases, with a negative UV continuum slope, to highly attenuated LAEs, with a positive UV continuum slope. The rest-frame optical-to-UV colors also show a significant variation from blue to red objects. This way, analyzing individual SEDs for each object, we find LAEs with very different properties, rather than the double nature suggested in previous works, which could be the result of the stacking method being employed (Lai et al., 2008; Gawiser et al., 2006, 2007). Actually, Nilsson et al. (2011) studied the effects of stacking in their sample of LAEs at $z \sim 2.3$, finding that, while stellar masses are robust to stacking, ages and dust attenuation tend to be incorrectly determined. Therefore, it is clear that to analyze the physical properties of LAEs at high redshift, individual fits to the observed photometry are needed, although it is challenging for those LAEs at $z \gtrsim 3$ owing to photometric limitations. Actually, only a few LAEs of the samples of Ono et al. (2010) and Lai et al. (2008) are detected in the

Ks band, which, at their redshifts, is quite important for sampling the Balmer break and obtaining accurate values of age and mass. Results based on stacking analysis must be taken with care, most importantly in those cases where the SEDs are known to have very diverse shapes and properties, as shown in this and previous works to happen at $2.0 \lesssim z \lesssim 3.5$ (Guaita et al., 2011; Nilsson et al., 2011).

As mentioned in Section 1, the spectroscopic selection used in this work allows isolating sources with Ly α $\text{EW}_{\text{rest-frame}} < 20 \text{ \AA}$ (non-LAEs). However, the number of such sources in our sample is low. Non-LAEs are also represented in Figure 3. It can be seen that the age, SFR and mass of these galaxies are in the same range as those for LAEs. The main difference is the dust attenuation: objects with an attenuated Ly α emission are among the dustiest objects in the sample. This points towards the idea that LAEs are among the least dusty galaxies at each redshift, as reported in other works for different redshifts (Cowie et al., 2011; Oteo et al., 2011a,b; Pentericci et al., 2007, 2010; Kornei et al., 2010).

Figure 4 represents the locus of Lyman Break Galaxies (LBGs) at $z \sim 3.0$ for the filters in the MUSIC survey (Pentericci et al., 2010). It can be seen that most LAEs at $z \gtrsim 2.75$ could have been also selected as LBGs. Most LAEs at $z \lesssim 2.75$ do not meet the LBG criterion, because for those redshifts, the Lyman break is not located between the U and V bands, but in bluer wavelengths. The subsample of LAEs with colors of LBGs (LAE-LBGs) is the bridge population between these two kinds of galaxies. The principal difference between LAE-LBGs and the total sample of LAEs is the dust attenuation: LAE-LBGs

tend to be dustier than other LAEs. In Figure 4, this tendency is reflected in their V-I color. At our redshifts, this color measures the UV continuum slope, and higher values correspond to greater dust attenuation. LAE-LBGs have higher V-I color (redder UV continuum) than other LAEs of the sample, since they are dustier. Pentericci et al. (2010) find that LBGs with a Ly α emission at our redshift have lower dust attenuation than those without a Ly α line. The combination of both results points toward a sequence of increasing dust attenuation, from the less-dusty non-LBG LAEs, to dustier LAE-LBGs, and finally those LBGs without Ly α emission, so they could be the same population differentiated by dust attenuation.

5. Morphology

By using HST/ACS images in GOODS-South we carried out a morphological analysis of the 56 studied Ly α emitting galaxies. We adopted the classification given in Elmegreen et al. (2009), and visually classify them into three groups: 37 clump clusters (CC), 8 chain galaxies (CH), and 11 spiral-bulges (SPB). This classification was done by three different people and the results were similar in the three cases. There is a wide variety of sizes and morphologies, from highly compact to highly clumpy objects. This heterogeneity in morphology is compatible with the wide range of physical properties for our LAEs reported in the previous section, indicating that galaxies segregated by their Ly α emission at our redshift do not have specific properties, but instead can be very diverse.

We fit the SPB LAEs, which are all at $z < 2.75$, with Sersic (1968) profiles by using GALFIT (Peng et al., 2010) in the z-band images. At our redshift, this band represents the emission of the rest-frame optical light near the Balmer break. The Sersic profiles can be analytically described by

$$I(r) = I_b(0) \exp \left[-b_n \left(r/R_{\text{eff}} \right)^{1/n} \right] \quad (1)$$

where $I_b(0)$ is the central intensity, R_{eff} the effective radius, and n the Sersic index. Figure 5 shows how GALFIT performs the fittings in three randomly selected SPB LAEs, which are representative of the behavior of the total sample of SPB LAEs. It can be seen that the Sersic (1968) profiles describe the morphology of these objects quite well. To obtain the intrinsic R_{eff} in kpc from the output value given by GALFIT (in pixels), we made use of the assumed cosmology and the ACS pixel scale. As the result, we find that the SPB LAEs have effective radii ranging from 2.6 to 3.1 kpc. The uncertainty in the effective radius, which is provided by GALFIT, is less than 5%. This range is compatible with the tail of the distribution at large effective radii found in Bond et al. (2009) at $z \sim 3.1$, in Bond et al. (2011) at $z \sim 2.1$, and in Oteo et al. (2011b) at $z \sim 0.3$. Therefore, an evolution in the physical sizes of LAEs with redshift is not seen with the present data.

Regarding the Ly α EW_{rest-frame}, we do not find any significant difference in the morphology of LAEs and non-LAEs, because of the scarcity of galaxies in the non-LAE sample. At $z \sim 0.3$, in Oteo et al. (2011b) we find that LAEs and non-LAEs have a clear difference in their morphology, both in shape and size, which indicates that at that redshift Ly α photons are escaping from small and irregular/merging galaxies. However, Pentericci et al. (2010) show that at our redshift, the rest-frame UV morphology does not depend strongly on the presence of the Ly α emission.

6. *Herschel* FIR counterparts

GOODS-South was observed with PACS-70 μ m, PACS-100 μ m, and PACS-160 μ m in the frame of the PACS Evolutionary Probe project (PEP, PI D. Lutz). PEP is the *Herschel* Guaranteed Time Key-Project designed to obtain the best profit from *Herschel* instrumentation to study the FIR galaxy population (Lutz et al., 2011). PACS fluxes used in this work were extracted using MIPS-24 μ m position priors with, at least, a 3σ significance. Limiting fluxes in PACS-70 μ m, PACS-100 μ m, and PACS-160 μ m are 1.0mJy, 1.1mJy, and 2.0mJy, respectively. We look for possible FIR counterparts of our galaxies within 2'', which is the typical astrometric uncertainty in the position of the sources, finding four detections in at least the PACS-160 μ m band. These counterparts are direct evidence of dust emission in high-redshift SF sources. As seen in Figs. ??, ?? and ??, GOODS_LRb_001_q2_9_1, GOODS_LRb_001_q3_9_1, and GOODS_LRb_001_q1_8_1 are isolated sources and, therefore, the dust emission is coming entirely from these sources. However, GOODS_LRb_dec06_3_q3_60_1 has a nearby galaxy whose emission in the FIR could contaminate the FIR flux of this galaxy. Two of the PACS-detected galaxies are within the LAE group and the other two have Ly α EW_{rest-frame} compatible with their being non-LAEs. Figure 6 represents the rest-frame UV to FIR SED of the four PACS-detected galaxies.

Table 1 shows the dust attenuation and SFR_{UV,uncorrected} of the four PACS-detected galaxies, as derived from SED fitting. Their rest-frame UV to mid-IR SEDs are compatible with high values of dust attenuation, and the two LAEs also exhibit greater SFR_{UV,uncorrected} than the median value of the sample. Their large SFR_{UV,uncorrected} indicates that they have high value of UV luminosity, compatible with the greater likelihood that UV-bright galaxies are detected in the FIR (Reddy et al., 2010). GOODS_LRb_001_q2_9_1, GOODS_LRb_001_q3_9_1, and GOODS_LRb_dec06_3_q3_60_1 are young objects with masses similar to the median population. However, GOODS_LRb_001_q1_8_1 is an old and dusty LAE, and it is among the most massive objects of the sample. This is one of the most interesting galaxies in our sample, since its physical properties are opposite the classical idea of an LAE, i.e. a young, less massive, and dust-free galaxy. Three out of the

four PACS-detected galaxies would have been selected via the Lyman break technique (see Figure 4). The other PACS-detected source would have not been segregated as LBG either, since its redshift is not high enough to place the Lyman break between the U and V filters. It can be seen that PACS-detected sources have among the highest V-I colors of the total sample, indicating that they have a high-attenuated UV continuum, compatible with being among the dustiest galaxies in our sample.

6.1. IR luminosities

Accurate values of the total 8-1000 μ m IR luminosities, L_{IR} , can be obtained for the PACS-detected galaxies. Since we do not have full coverage of the dust emission peak, we cannot calculate L_{IR} by direct integration of the FIR SED. Instead, we convert PACS fluxes into L_{IR} by using Chary & Elbaz (2001) (hereafter CE01) templates, which have only one solution for L_{IR} for each FIR flux and redshift. Obtaining L_{IR} by using single FIR band extrapolations has been employed with successful results in previous works in galaxies at similar redshifts (Nordon et al., 2010; Elbaz et al., 2010, 2011). In fact, Elbaz et al. (2010) combine PACS and SPIRE measurements to show that fitting CE01 templates to the PACS-160 μ m flux provides reliable estimates of L_{IR} at our redshift. The typical uncertainties of the derived values are related to the accuracy of single band extrapolations rather than to the uncertainties of the PACS fluxes themselves, and are typically less than 0.2 dex (Elbaz et al., 2011). Actually, for galaxies in our redshift range, PACS-160 μ m band extrapolations give the most accurate results for single band extrapolations (Elbaz et al., 2010).

6.2. LAE-ULIRGs relation

Previous results suggest that some LAEs at our redshift range are also ultraluminous infrared galaxies (ULIRGs) (Nilsson & Møller, 2009; Nilsson et al., 2011; Ono et al., 2010; Chapman et al., 2005), but direct detections in the FIR around the dust emission peak have not been reported yet. In the present work, according to their L_{IR} , the four PACS-detected galaxies have an ULIRG nature. Owing to the depth of the PACS observations used in this work, the limiting L_{IR} is about $10^{12} L_{\odot}$ at $z \sim 2.2$. Therefore, there could be some PACS-undetected LAEs in our sample, the dustiest at the highest redshifts, that fall in the ULIRG class. Actually, given that FIR detections segregate dusty galaxies, it is expected that the dustiest LAEs, $E(B-V) \geq 0.2$ of the sample have an ULIRG nature even when PACS-undetected. Thus, more LAEs with an ULIRG nature should be expected. The number of LAEs with an ULIRG nature found, although scarce, is very important. In Oteo et al. (2011a,b) we studied the FIR properties of a sample of 23 mid-IR/FIR detected LAEs at $z \sim 0.3$, finding that most LAEs are in the normal SF galaxy regime, $L_{IR} < 10^{11} L_{\odot}$, with only one having $L_{IR} \sim 10^{11.5} L_{\odot}$, and none above that value. The discovery of LAEs with an ULIRG nature at $z \sim 2.4-2.8$ suggests that the IR properties of LAEs evolve from $z \sim 0.3$ to ~ 2.5 in the sense that there is a population of red and dusty LAEs that is not seen at lower redshifts. Therefore, we find from direct FIR detections that the ULIRG fraction in LAEs decreases from $z \sim 2.4-2.8$ to ~ 0.3 , following the trend found for IR-detected galaxies between those redshifts (Le Floc'h et al., 2005).

This possible evolution of the IR emission, along with the reported evolution in the UV luminosity (Section 4) and in the Ly α luminosity function from $z \sim 1.0$ (Cowie et al., 2011), indi-

cates that either the Ly α selection technique does not trace the same kind of objects with redshift, or the properties of Ly α selected galaxies change with redshift.

6.3. Dust attenuation

The ratio between IR and UV luminosities is the best way to obtain the dust attenuation in galaxies. Adopting the Buat et al. (2005) calibration, the dust attenuation for our PACS-detected Ly α emitting galaxies can be obtained with the expression

$$A_{NUV} = -0.0495x^3 + 0.4718x^2 + 0.8998x + 0.2269 \quad (2)$$

where, $x = \log(L_{IR}/L_{NUV})$. The conversion from dust attenuation in NUV band into the color excess in the stellar continuum is carried out by using the Calzetti et al. (2000) reddening law. The values obtained are shown in Table 1. PACS-detected LAEs have high values of dust attenuation and, since they are selected via their IR emission, those values represent an upper limit in dust attenuation of LAEs in the studied redshift range. This is a direct indication from FIR measurements that the Ly α emission and the presence of dust are not mutually exclusive. This result could reinforce the scenario where the Ly α emission can be enhanced under a suitable geometry (Neufeld, 1991), for which evidence has already been found at higher redshifts (Finkelstein et al., 2008), but not at our redshift or lower (Guaita et al., 2011; Finkelstein et al., 2011). The dust attenuation derived from SED-fitting tends to be lower than obtained from direct IR/UV measurements. The ULIRG nature plays an important role in this underestimation, since for such as sources, the IR emission is more prominent than in other less IR luminous galaxies, and its inclusion in the analysis is essential to obtaining accurate results.

6.4. SFR

The combination of UV and IR luminosities provides the best determination of the SFR in galaxies. Assuming that all the light absorbed in the UV is in turn reradiated in the FIR, the total SFR of a galaxy, SFR_{total} , can be obtained as the sum of $SFR_{UV,uncorrected}$ plus a correction term associated to the dust emission in the FIR. Adopting the Kennicutt (1998) calibration, that correction term can be written as

$$SFR_{IR}[M_{\odot}yr^{-1}] = 4.5 \cdot 10^{-44} L_{IR} [\text{erg s}^{-1}] \quad (3)$$

where L_{IR} is defined in the same way than in Section 6.1. In this way, SFR_{total} can be inferred from

$$SFR_{total} = SFR_{UV,uncorrected} + SFR_{IR}. \quad (4)$$

The values of SFR_{total} obtained for the PACS-detected galaxies are also shown in Table 1. Such sources have high SFR_{total} , all above $200 M_{\odot}yr^{-1}$. PACS-detected sources are the reddest ones of the sample and the fastest star formers. Although the number of such kind of galaxies is low, their SFRs can therefore be considered as the maximum value of SFRs for LAEs in this redshift range. It can be also seen that the contribution of the SFR_{IR} to the SFR_{total} is quite high, above 93% in all cases, and, therefore, SED fitting with BC03 templates, which do not take the dust emission in the FIR into account, systematically underestimates this quantity. Since we do not have a statistically significant sample of LAEs detected in the FIR, we cannot evaluate a typical factor of underestimation for LAEs in our redshift range.

Table 2. Total infrared luminosities for the MIPS-24 μ m detected LAEs. PACS-detected LAEs, which are also detected in MIPS-24 μ m are not included in this table.

Object	Redshift	Log(L_{IR}/L_{\odot})
GOODS_LRb_002_1.q3_8_1	2.296	12.34
GOODS_LRb_002_1.q2_60_1	2.181	11.30
GOODS_LRb_dec06_2.q2_12_1	2.318	12.10
GOODS_LRb_dec06_3.q1_21_1	2.230	11.97
GOODS_LRb_002_1.q4_66_1	2.586	12.29
GOODS_LRb_dec06_3.q4_53_1	2.702	11.62

In Oteo et al. (2011b) we found that, for LAEs at $z \sim 0.3$, the contribution of the FIR emission is more than 60% in most cases, so that SFR based on SED fitting is underestimating the SFR by a factor greater than 2. According to the IR evolution reported in Section 6.2, it could be expected that the FIR contribution can be higher than 60% for a high percentage of the sample. Actually, LAEs at $z \sim 2.0$ with $L_{IR} \gtrsim 10^{10.5} L_{\odot}$ are unlikely to be detected with the current FIR surveys, and their IR contribution to the SFR_{total} , assuming a $SFR_{UV,uncorrected} \sim 10 M_{\odot} yr^{-1}$, is about 50%.

By using the dust attenuation derived from SED fitting, we can correct the $SFR_{UV,uncorrected}$ of the PACS-detected sources to estimate the SFR_{total} . Their values are also shown in Table 1. It can be seen that the SFR_{total} obtained in such a way are much lower than the values obtained from the IR emission. This agrees with Wuyts et al. (2011), who find that SED fitting tend to underestimate the total amount of star formation in IR-bright galaxies at $z \gtrsim 2.5$.

6.5. MIPS-24 μ m counterparts of LAEs

In addition to the analyzed measurements in PACS-160 μ m, six other PACS-undetected galaxies of the total sample of 144 have MIPS-24 μ m detections in the FIR regime, which were found following the same criterion as used for PACS counterparts. All these galaxies are classified as LAEs. None of them are within the MUSIC footprint, so we cannot analyze the distinctive properties of MIPS-24 μ m-detected LAEs regarding the rest-frame UV to mid-IR SED fitting. The MIPS-24 μ m detections also indicate the presence of IR-bright, i.e. dusty, LAEs. At $2.0 \lesssim z \lesssim 3.5$, the MIPS-24 μ m band has a significative contribution of PAH molecule emission, which does not allow us to determine the L_{IR} for MIPS-detected LAEs. Actually, Elbaz et al. (2010) study the validity of MIPS-24 μ m extrapolations to the L_{IR} , finding that they are valid up to $z \sim 1.5$ and for objects that are below the ULIRG limit. At $z \gtrsim 1.5$, MIPS-24 μ m extrapolations tend to overestimate the L_{IR} in a factor of about 2 or 3. Despite this overestimation, we show the L_{IR} luminosities for the MIPS-24 μ m detected LAEs in Table 2 as inferred from MIPS-24 μ m single band extrapolation, in a similar way to Sect. 6.1 for PACS-detected sources. Owing to the PACS catalogs used in Section 6, PACS-detected LAEs are also detected in MIPS-24 μ m but we do not consider those objects here because they have been more accurately studied in previous sections. It can be seen in Table 2 that, although overestimated, MIPS-24 μ m detected LAEs have high values of L_{IR} , placing them in, at least, the LIRG regime, $L_{IR} > 10^{11} L_{\odot}$. Therefore, in total we gather a sample of ten red and dusty LAEs, which are opposite to the classical idea of LAEs as dust-free galaxies.

7. Summary and conclusions

In this work we have analyzed the rest-frame UV to IR SED of a sample of 56 *Ly α* emitting galaxies at $2.0 \lesssim z \lesssim 3.5$. According to their *Ly α* $EW_{rest-frame}$ we distinguish between LAEs and non-LAEs as those *Ly α* emitting galaxies with *Ly α* $EW_{rest-frame}$ above and below 20 \AA , respectively. This value is the typical threshold in narrow-band searches. Our main conclusions are as follows.

1. Individual SED fittings for the studied LAEs indicate that they are mostly young galaxies with ages below 100 Myr, although some of them have SEDs compatible with populations older than 300 Myr. The dust attenuation ranges from low, $E(B-V) \sim 0.0$, to high values, $E(B-V) \sim 0.3$, with a median of $E(B-V)$ of 0.15. The SFRs, as derived from UV dust-uncorrected measurements, range from about 2 to 100 $M_{\odot} yr^{-1}$, mostly having $SFR_{UV,uncorrected} \sim 10 M_{\odot} yr^{-1}$.
2. We find that LAEs at $2.0 \lesssim z \lesssim 3.5$ show a wide range of properties, rather than having a double nature as suggested in previous works. This result has been possible to achieve because our LAEs are continuum-bright objects and, therefore, an individual SED fitting for each source could be carried out.
3. The variety of the physical properties of LAEs is also reflected in their morphology. We find many different structures, from bulge-like galaxies to highly clumpy systems or chain galaxies. Fitting the bulge-like LAEs to Sersic profiles, we found sizes distributed within 2.6 and 3.1 kpc, compatible with those reported in other works at higher, similar and lower redshifts.
4. We find four *Ly α* emitting galaxies with PACS-FIR counterparts, two LAEs, and two non-LAEs. This indicates that some LAEs have such high dust content that their emission can be directly detected. Their rest-frame UV to mid-IR SEDs are compatible with objects with high dust attenuation. FIR-detected LAEs are objects with high SFR, above $200 M_{\odot} yr^{-1}$, and their L_{IR} classify them as ULIRGs. LAEs with an ULIRG nature are not seen at $z \sim 0.3$, suggesting that there is an evolution in their IR emission with redshift. This, along with the rapid evolution of the *Ly α* luminosity function from $z \sim 0.3$ to ~ 1.0 reported in previous works and the evolution in the L_{UV} from $z \sim 0.3$ to $z \gtrsim 2.0$ found here indicates that either the physical properties in the UV, optical, and IR of objects that are selected via their *Ly α* emission change with redshift or else the *Ly α* selection technique would segregate different types of galaxies at different redshifts.
5. We obtain the dust attenuation in the PACS-detected LAEs with MUSIC counterparts by combining UV and FIR information, without the uncertainties of the SED-fitting based methods. The results obtained in this way show that they have color excesses greater than 0.30 in their stellar continuum. This indicates that PACS-detected LAEs are dusty objects, despite having a *Ly α* line emission in their spectra. This confirms from direct FIR observations that dust and *Ly α* emission are not mutually exclusive.
