ABSTRACT
Defining, prioritizing, and selecting requirements are problems of tremendous importance. In this paper, a new approach called Quantitative WinWin for decision support in requirements negotiation is studied. The difference to Boehm’s WinWin groupware-based negotiation support is the inclusion of quantitative methods as a backbone for better and more objective decisions. Like Boehm’s original WinWin, Quantitative WinWin uses an iterative approach, with the aim to increase knowledge about the requirements during each iteration. The novelty of the presented idea is three-fold. Firstly, it uses the Analytical Hierarchy Process for a stepwise determination of the stakeholders’ preferences in quantitative terms. Secondly, these results are combined with methods for early effort estimation, in our case using the simulation prototype GENSIM, to evaluate the feasibility of alternative requirements subsets in terms of their related implementation efforts. Thirdly, it reflects the increasing knowledge gained about the requirements during each iteration, in a similar way as it is done in Boehm’s spiral model for software development. As main result, Quantitative WinWin offers decision support for selecting the most appropriate requirements based on the preferences of the stakeholders, the business value of requirements and a given maximum development effort.

Requirements negotiation, decision support, quantitative methods, analytical hierarchy process, effort estimation, simulation, Easy WinWin

1. BACKGROUND-AND MOTIVATION
Software development is a very complex, often distributed process with a variety of process and product attributes, as well as numerous functional and non-functional objectives and constraints. Brooks [5] describes the importance of selecting and describing the right requirements: “The hardest single part of building a software system is deciding precisely what to build.” Typically, requirements are imprecise or incomplete at the beginning of the life cycle and are becoming more and more complete and precise as development progresses. A further complication is that the various stakeholders have different perspectives of and expectations on a system, i.e., they assign varying priorities to requirements. Marketing and project managers also struggle with a lack of a clear understanding of the relationship between a selected set of requirements and the effort required for its implementation. The overall effort that can be spent on the project is limited and the time to market of the final product is constrained. The challenge is to select the ‘right’ requirements out of a given superset of candidate requirements so that all the different key interests, technical constraints and preferences of the critical stakeholders are fulfilled and the overall business value of the product is maximized.

Development support for software projects currently available includes numerous design tools, configuration management tools and requirements management tools. Over the last few years, these tools have helped improve software quality and are now in wide spread use in industry. However, they are domain-independent, i.e., they cannot provide domain-specific support. Furthermore, while many of these tools have been successful in providing support for modeling and code generation, they have been less successful in supporting requirements analysis [9].

Domain-specific support is difficult to provide. The requirements engineering community has developed some research tools [7], [13] that provide domain-specific assistance. However, such tools are not widely used in industry. The main reasons for this are the effort required to initially model the domain in sufficient detail as well as the effort required for keeping the domain models up-to-date. Any changes at higher levels of abstraction would cause major changes in the domain models. Considering the rapid changes in today’s domains, this approach appears to become less and less feasible.

The distributed nature of system development has resulted in several approaches that provide collaboration support. The most common ones are telephone and video conferencing facilities. Various groupware systems are also in use. Boehm et al. [2] have created a prototype for his WinWin spiral model, a tool that assists stakeholders in creating win-win solutions for all parties involved. Furthermore, research is being done in the general area of computer support for decision-making groups involved in the negotiation of requirements over a distance. Damian et al. particularly investigate the effect of the communication media (audio, video, etc.) on the negotiation outcome [6].

Unfortunately, there is so far no comprehensive support for making decisions throughout software development. Such decision support would be most helpful when decisions have to be made in complex and dynamic environments. Support here means assistance for structuring the problem, for analyzing and verifying
the obtained structure, as well as help for comparing the results of different choices using simulation. Decision makers need support to describe, evaluate, sort, rank, select or reject candidate products, processes or tools.

In this paper, a new approach called Quantitative WinWin for decision support in requirements negotiation is studied. The difference to Boehm’s WinWin groupware-based negotiation support is the inclusion of quantitative methods. Like Boehm’s original WinWin, Quantitative WinWin uses an iterative approach, with the aim to increase knowledge about the requirements in each during all iteration. A key feature of the quantitative approach is the elicitation of implicit preferences of involved stakeholders using Analytical Hierarchy Process (AHP). The combination of AHP with effort estimation using modeling and simulation, as well as the stepwise inclusion of requirements into the requirements subset to be implemented provides comprehensive assistance for the selection of optimal requirements with respect to the trade-off between business value and development effort.

The paper is organized as follows: Section 2 provides definitions and assumptions as well as a mathematical description of the problem. Section 3 explains the methodological underpinnings used in our approach, namely the incremental treatment of requirements, the use of Analytic Hierarchy Process (AHP) to assign priorities to stakeholders and the different requirements classes, as well as the computation of optimal trade-offs for subset selection under resource constraints. Section 4 presents the simulation model GENSIM that is used in section 6 for effort estimation and an initial validation of the Quantitative WinWin approach considering three stakeholders and three classes of requirements. The overall quantitative WinWin approach is described in detail in section 5. Finally, a summary and conclusions are given at section 7.

2. UNDERLYING ASSUMPTIONS AND PROBLEM STATEMENT

2.1 Classes of Stakeholders and Requirements

For the purpose of this paper we assume a set $\mathcal{R} = \{r_1, \ldots, r_n\}$ of requirements $r_1, \ldots, r_n$. The set $\mathcal{R}$ is subdivided into $q$ disjoint subclasses $\mathcal{R}_1, \mathcal{R}_2, \ldots, \mathcal{R}_q$ ($q<n$) of requirements, e.g., $\mathcal{R} = \mathcal{R}_1 \oplus \mathcal{R}_2 \oplus \ldots \oplus \mathcal{R}_q$. The rational for this assumption is that requirements can be classified according to their resource needs, their interaction (two requirements interact if and only if the satisfaction of one requirement affects the satisfaction of the other [14]) and their purpose. Each class contains requirements of the same type. Example classes are requirements related to the user interface, or non-functional requirements like reliability or maintainability. Each requirement $r_i$ is assumed to belong to exactly one class. Mapping $\psi(i)$ assigns each requirement $r_i \in \mathcal{R}$ to the associated class $\mathcal{R}_{\psi(i)}$.

Another important assumption addresses the importance of requirements. Some of the given requirements are mandatory and related to the core functionality of the system. Others are more or less optional. We assume that each requirement $r_i$ has a relative importance $\alpha(r_i)$ $\in$ $(0,1]$ within class $\mathcal{R}_{\psi(i)}$. That is defined on a rational scale. $\alpha(r_i) = 1$ means that the requirement is mandatory.

On the other hand, $\alpha(r_i)$=$2\alpha(r_i)$ means that requirement $r_i$ is twice as important than requirement $r_j$. These relative importance factors within each class are assumed to be objective, i.e., independent of the different stakeholder perspectives.

One of the challenges of requirements engineering is that the different stakeholders of a system usually have conflicting viewpoints and preferences. To reflect and model this situation, we introduce different classes of stakeholders. The $p$ classes are abbreviated by $S_1, S_2, \ldots, S_p$. Later we will use the Analytical Hierarchy Process (AHP) to elicit the stakeholders’ preferences regarding the different classes of requirements (not the individual requirements contained in the classes). In the worst case, these preferences can still change over time. This issue is addressed by the iterative nature of our overall approach.

Example stakeholders are novice, advanced or expert users as used in the example described in section 6. Other stakeholders can be e.g., managers (having a business-driven perspective) or developers (having a more technical perspective). In any case, different classes of stakeholders will have different objectives and ideas for developing, using and handling the final software product.

2.2 Problem Statement

The original set of requirements $\mathcal{R}$ is considered to be a superset containing the requirements of all stakeholders involved. Because resources are limited, the challenge is to find those subsets of requirements that can be implemented without exceeding the given effort maximum. For that reason, we define an upper effort bound denoted by EFFORT. We then need to assign to each subset $\mathcal{R}^*$ $\subseteq \mathcal{R}$ an estimated value called $\text{ef}(\mathcal{R}^*)$ which represents the estimated effort required for implementing the requirements subset $\mathcal{R}^*$. We can now formulate our implementation effort constraints as $\text{ef}(\mathcal{R}^*) \leq \text{EFFORT}$.

Typically, estimates for $\text{ef}(\mathcal{R}^*)$ are difficult to get and uncertain in their nature. Example estimation methods are (adjusted) function points [1], or simulation methods, such as system dynamics when combined with expert judgment during modeling [11]. For instantiation and illustration of the generic solution approach as presented in section 4, we assume that there is a simulation model based on system dynamics that is able to provide appropriate effort predictions.

In order to be able to select requirements subsets that maximize the business value in relation to its necessary implementation effort, the importance of the different classes of requirements from the perspective of the different stakeholders has to be determined. From the application of AHP, we assume a normalized vector of importance $\beta = (\beta(\mathcal{R}_1), \beta(\mathcal{R}_2), \ldots, \beta(\mathcal{R}_q))$ of the $q$ classes of requirements. The absolute importance $\chi(r_i)$ of each requirement $r_i$ is the product of the importance of the associated class $\mathcal{R}_{\psi(i)}$ with the relative importance $\alpha(r_i)$ of requirement $r_i$ within class $\mathcal{R}_{\psi(i)}$ i.e., $\chi(r_i) = \alpha(r_i) \cdot \beta(\mathcal{R}_{\psi(i)})$. With the notation introduced above we are now able to describe the problem “Requirements Subset Selection (RSS)” in a more formal way:

Requirements Subset Selection (RSS): Find all subsets of requirements $\mathcal{R}^* \subseteq \mathcal{R}$ such that

(1) $\text{ef}(\mathcal{R}^*) \leq \text{EFFORT}$,
The Analytic Hierarchy Process (AHP) [15] is a systematic approach to elicit implicit preferences between different attributes. For the purpose of this investigation, AHP is applied to determine the importance of the various stakeholders from a business perspective. In addition, it is used to prioritize the different classes of requirements from the perspective of each stakeholder. The two preference schemata are combined to rank the importance of the different classes of requirements for the final business value of the software product. The outcome of the two-step AHP analysis is used to determine most preferred (i.e., non-dominated) solutions R* at the t-th iteration which is reached when the given effort constraint is violated for the first time.

AHP assumes that the problem under investigation can be structured as anattributive hierarchy with at least three levels. At the first level, the overall goal is described. The second level describes the different competing criteria that refine the overall goal of level 1. Finally, the third level is used for the selection from competing alternatives.

### 3. HYBRID AND QUANTITATIVE APPROACH TO SUPPORT REQUIREMENTS SUBSET SELECTION

This section describes a new approach for stepwise requirements subset selection called Quantitative WinWin. The overall method for solving RSS consists of three main components that are described in more detail in the subsequent parts of this section:

- Analytic Hierarchy Process (AHP)
- Stepwise relaxation of the required importance level of candidate requirements
- Optimal trade-offs for requirements subset selection under given resource constraints

The combination of these techniques helps to find subsets of requirements that represent optimal trade-offs between effort and overall business value. As a result, the actual decision maker can finally choose from a set of pairwise incomparable points of a trade-off curve (see also the validation example and Fig 6).

The novelty of the presented idea is three-fold. Firstly, it uses AHP for a stepwise determination of the stakeholders’ preferences in quantitative terms. Secondly, these results are combined with methods for evaluating the feasibility of selected subsets of requirements in terms of their implementation effort. Thirdly, it reflects the increasing degree of knowledge gained about the requirements in each iteration in the same way as it is done in Boehm’s spiral model [3] for software development. Even though inherently difficult, we assume that an effort estimation method can be applied based on a given specification of requirements. As discussed in [4], estimation is increasingly based on a combined use of expert opinion and simulation. In section 4, we describe how the simulation model GENSIM (GENeric SIMulator) is used for the purpose of effort estimation. The GENSIM model allows the simulation of the software development process from the end of the requirement analysis step down to the end of system testing.

#### 3.1 Analytic Hierarchy Process

![Figure 1. Example AHP graph for optimal requirements selection.](image)

In the context of this paper, the first level corresponds to the maximum business value of the final software product. In general, there are p nodes in the second level that correspond to the p stakeholders. In the same way, the q nodes at the third level are associated with the q classes of requirements assumed. If necessary, a fourth level can be introduced used for a further refinement of the classes of requirements. The triangles indicate the way attributes of one level are assessed from the perspective of the parent node. This is shown in Figure 1.

At each level of the hierarchy, a decision-maker performs a pair-wise comparison of attributes assessing their contributions to each of the higher level nodes to which they are linked. This pairwise comparison involves preference ratios (for actions) or importance ratios (for criteria). The expert assigns an importance number that represents the importance of a term ti with respect to another term tj to describe the domain. Saaty [15] introduced a nine-point intensity scale:

- Of equal importance \(\rightarrow\) preference number=1
- Of moderate importance \(\rightarrow\) preference number=3
- Of strong importance \(\rightarrow\) preference number=5
- Of very strong importance \(\rightarrow\) preference number=7
- Of extreme importance \(\rightarrow\) preference number=9.

To get a ranking of priorities from a set of attributes, the best approach is the eigen-value solution [15]. From iterative application of this procedure, we receive the weights of importance of each requirement of the domain with respect to the overall business goal. There exist commercially available tools that compute the eigen-values and check the degree of consistency between the pair-wise comparisons. For the computations of the example in section 6, we used a tool called ExpertChoice [17].
3.2 Incremental Refinement of Requirements Selection

An iterative approach for the incremental refinement of requirements and resource constraints is chosen to reflect the impreciseness of requirements and their dynamically changing character. The motivation for the stepwise inclusion of more requirements is two-fold.

Firstly, requirements are typically uncertain at the beginning, and become more and more precise during the software life cycle. This is explicitly assumed in the spiral software development model, but is valid to some extend also for other software development paradigms. Consequently, requirements selection has to become increasingly precise. At the beginning, the focus is on the most important requirements, i.e., those requirements with largest value $\chi(r_i)$. Later, conditions are gradually relaxed to include as many requirements with lower importance as possible until the maximum effort bound is reached.

Secondly, as another indication of incompleteness and impreciseness of requirements, it may happen that new requirements are added during (spiral) software development. This is reflected by the iterative approach where you can consider additional requirements for inclusion that appeared at a later stage of development.

The idea is to consider a sequence $\{\text{RSS}^i\}_{i=1,\ldots,s}$ of problems of type RSS. However, only the final one is solved explicitly. The different problems are characterized by different sets of requirements $\{\mathcal{R}^i\}_{i=1,\ldots,s}$. Assume there is a monotonously decreasing sequence $\{\text{level}^i\}_{i=1,\ldots,s}$ of levels of minimum importance $\chi(r_i)$. The set $\mathcal{R}^i$ is defined as the set of requirements with weighted importance of being at least level^i, i.e., $\mathcal{R}^i = \{r_i \in \mathcal{R} : \chi(r_i) \geq \text{level}^i\}$. This implies that $\mathcal{R}^1 \subseteq \mathcal{R}^2 \subseteq \ldots \subseteq \mathcal{R}$. The number $\tau$ of iterations is defined as the first iteration at which the total amount of effort would exceed the specified maximum value EFFORT, i.e. too many candidate requirements have been selected for implementation. In this case, the approach described in section 3.3 for requirements subset selection under given resource constraints is applied.

3.3 Optimization of Requirements Selection

We assume that at the $\tau$-th iteration the given effort constraint is violated for the first time, i.e., $\text{eff}(\mathcal{R}^\tau) > \text{EFFORT}$ and $\text{eff}(\mathcal{R}^{\tau+1}) \leq \text{EFFORT}$. Problem $\{\text{RSS}^\tau\}$ is a discrete optimization problem with a non-linear and non-additive effort function $\text{eff}: \mathcal{R} \Rightarrow \text{eff}(\mathcal{R})$ that cannot be formulated explicitly. We use an enumeration algorithm to determine those sets of requirements that maximize the effort and are non-dominated. A solution with two objectives (in our case, effort and business value) is called non-dominated if there is no other (feasible) solution that strictly better in one criterion and not worse in the other one. In our case, the set of non-dominated solutions is abbreviated by $\Gamma$. To compute $\Gamma$ we systematically eliminate requirements from the infeasible set $\mathcal{R}^\tau$ and check the feasibility of the resulting set. Finally, a consistency check within $\Gamma$ is conducted to make sure that no solution within $\Gamma$ is dominated by another one. The recursive procedure with input set $\mathcal{R}^\tau$ can now be described as follows:

**Algorithm RSS($\mathcal{R}^\tau$)**

begin
\[ \Gamma = \emptyset \]
for all $\mathcal{R}_k \in \mathcal{R}^\tau$ do
begin
if $\text{eff}(\mathcal{R}^\tau \setminus \{\mathcal{R}_k\}) \leq \text{EFFORT}$
then $\Gamma = \Gamma + \{\mathcal{R}^\tau \setminus \{\mathcal{R}_k\}\}$ else RSS($\mathcal{R}^\tau \setminus \{\mathcal{R}_k\}$)
end
for all $\mathcal{R}^\ast \in \Gamma$ do
begin
if there is a feasible set $\mathcal{R}^\ast \in \Gamma$ such that
either $\text{eff}(\mathcal{R}^\ast) < \text{eff}(\mathcal{R}^\ast) \& \sum_{r \in \mathcal{R}^\ast} \chi(r) \geq \sum_{r \in \mathcal{R}^\ast} \chi(r)$
or $\text{eff}(\mathcal{R}^\ast) \leq \text{EFFORT} \& \sum_{r \in \mathcal{R}^\ast} \chi(r) > \sum_{r \in \mathcal{R}^\ast} \chi(r)$
then $\Gamma = \Gamma \setminus \mathcal{R}^\ast$
end
end

4. EFFORT ESTIMATION USING “GENSIM”

In order to generate estimates of $\text{eff}(\mathcal{R})$ we used the simulation model GENSIM (GENeric SIMulator) [12]. As has been mentioned before, the GENSIM model can be used for the simulation of the software development process from the end of the requirement analysis step through to the end of system testing (cf. Figure 2). Although the model is only a research prototype it can be easily calibrated to product and process measures of a specific organization in order to capture the behaviour of each development cycle in Boehm’s spiral model. The model has successfully been used for the simulation of processes in various companies. For producing the effort estimates used in the example in section 6 of this paper, GENSIM was calibrated to the development process of a fictitious software organization. The GENSIM model has a modular structure. It consists of five interrelated sub-models:

**Production:** This sub-model represents a typical software development cycle consisting of the following steps of transitions: set of requirements $\rightarrow$ design documents $\rightarrow$ code $\rightarrow$ tested code. Note that the detection of defects during testing only causes reworking of the code (and not of the design documents).

**Quality:** In this sub-model, the defect co-flow is modeled, i.e.: defect injection (into design or code) $\rightarrow$ defect propagation (from design to code) $\rightarrow$ defect detection (in the code during testing) $\rightarrow$ defect correction (only in the code).

**Effort:** In this sub-model, the total effort consumption for design development, code development, code testing, and defect correction (rework) is calculated.

**Initial Calculations:** In this sub-view, the normal value of the central process parameter “productivity” is calculated. The normal productivity varies with assumptions about the product development mode (organic, semi-detached,
embedded) and characteristics of the project resources available (e.g., developer skill).

**Productivity, Quality & Manpower Adjustment:** In this sub-model, project-specific process parameters, like (actual) productivity, defect generation, effectiveness of QA activities, etc., are determined based on a)

1. planned target values for manpower, project duration, product quality, etc., and
2. b) time pressure caused by unexpected rework or changes in the set of requirements.

**Table 1. Input and output parameters of the GENSIM model.**

**Figure 2. Schematic representation of the product flow captured by the GENSIM production sub-model.**

A detailed description of the GENSIM model can be found in [12]. The most important input and output parameters are listed in Table 1. The input parameters of the simulation define the project goals (Product_size, Planned_completion_time, Goal_field_defect_density) and constraints (Average_complexity, Planned_manpower, Manpower_skill), as well as the process, e.g.,

- the degree to which design and code inspections are applied (Inspection_intensity_design, Inspection_intensity_code).
- The output parameters represent the simulation results, e.g., size of the work and end products (Design_size, Code_size, Product_size), project duration (Project_duration), effort consumption (Effort), and product quality (Field_defect_density).

For the calculations conducted in the example presented in section 6, all the input (and output) parameters with grey shading have been varied as part of the simulation runs.

The simulation runs.

In output) parameters with grey shading have been varied as part of conducted in the example presented in section 6, all the input (and product quality (Field_defect_density)). For the calculations work and end products (Design_size, Code_size, Product_size), output parameters represent the simulation results, e.g., size of the degree to which design and code inspections are applied (Planned_manpower, Manpower_skill), as well as the process, e.g. (Average_complexity, Planned_manpower, Manpower_skill), as well as the process, e.g.,

- the degree to which design and code inspections are applied (Inspection_intensity_design, Inspection_intensity_code).
- The output parameters represent the simulation results, e.g., size of the work and end products (Design_size, Code_size, Product_size), project duration (Project_duration), effort consumption (Effort), and product quality (Field_defect_density).

For the calculations conducted in the example presented in section 6, all the input (and output) parameters with grey shading have been varied as part of the simulation runs.

Even though System Dynamics has an increasing number of applications in the software engineering domain, it is by no means suggested to be the new silver bullet technique for problem solving. Instead, it is important to clarify the underlying assumptions for System Dynamics modeling and simulation. Only if these assumptions are valid, it is recommended to use the System Dynamics approach in a particular situation. The basic assumptions are:

- Problems under investigation are dynamic in nature and relate to systems with entities and attributes that are interconnected in loops of information feedback and circular causality.
- Sufficient maturity and stability of the software development processes in place in the organization, e.g., CMM level 3 or higher [10].
- Availability of expertise for identification of base mechanisms and construction of causal diagrams.
- Availability of data for model calibration.

These assumptions are valid for the requirements engineering process of most mature software organization. Requirements are very volatile and prone to numerous changes. If we assume a fairly mature software organization, the software development processes are well thought-through and reasonably stable, and thus hypotheses about base mechanisms should not be too difficult to elicit from experienced project managers – as long System Dynamics experts are available to conduct interviews and transform their input into causal diagrams. Mature organizations are also likely to have a metric collection process in place, i.e., there should be sufficient data available to calibrate the simulation models.

**5. QUANTITATIVE “WINWIN” – THE OVERALL ALGORITHM**

The algorithm called Quantitative WinWin uses iterative and hybrid application of the techniques described in section 3 and 4. We distinguish six consecutive steps, which are conducted in each iteration i as described in Figure 3. The number of iterations is not determined in advance. It depends on the degree of change in requirements during the development cycle and is finally determined by the expert using Quantitative WinWin for support in negotiating requirements.

**Step 1: Definition of the candidate set of requirements.**

At the beginning of each iteration i, the threshold value level defines a requirements subset that contains those requirements \( r_j \) of the original set \( \mathcal{R} \) that have a importance value of at least level, i.e., \( \mathcal{R}^i = \{ r_j \in \mathcal{R} : \chi(r_j) \geq \text{level} \} \). The threshold values are not defined in advance and have to be determined by experts. The
threshold value will determine the size of the set of requirements under investigation. The only assumption is that level \( l_{i+1} > \text{level}_i \) for all iterations \( i \). An other modification of the candidate set of requirements can be done by adding to \( \mathcal{R} \) further requirements at later iterations (as can be seen in the example in section 6).

**Step 2: Computation of preferences between involved stakeholders.**

Preferences are computed from the perspective of the overall business value. AHP is applied for that purpose (based on the nine-point scale introduced in section 3.1) resulting in a normalized vector of weights \( \text{weight}_0 = (\text{weight}_{0,1}, \ldots, \text{weight}_{0,q}) \) with \( \Sigma \text{weight}_{0,i} = 1 \).

**Step 3: Computation of preferences between requirements classes.**

Preferences are computed from the perspective of the individual stakeholders. AHP is applied for that purpose (based on the nine-point scale introduced in section 3.1) resulting in normalized vectors \( \text{weight}_1, \ldots, \text{weight}_q \).

**Step 4: Computation of overall preferences between requirements classes.**

Computation of overall preferences between requirements classes by consecutive application of the weights computed in step 3 (the vectors \( \text{weight}_1, \ldots, \text{weight}_q \) are arranged as the rows of a matrix \( M \)) and step 2 (column vector) by multiplication of matrix \( M \) with vector \( \text{weight}_0 \). The result is a vector of importance \( M \) and step 2 (column vector) by multiplication of matrix \( M \) with vector \( \text{weight}_0 \).

**Step 5: Refinement of candidate requirements.**

Subset \( \mathcal{R}' = \{ r_j \in \mathcal{R}: \chi(r_j) \geq \text{level}_i \} \) with \( \chi(r_j) = \alpha(r_j) \beta(R_{v0[i]}) \) is defined where \( \mathcal{R} = \mathcal{R} + \Delta \mathcal{R}' \) is the original set of requirements eventually extended by requirements \( \Delta \mathcal{R}' \) added in a later stage.

**Step 6: Effort estimation and feasibility check.**

For each subset \( \mathcal{R}' = \{ r_j \in \mathcal{R}: \chi(r_j) \geq \text{level}_i \} \) with \( \chi(r_j) = \alpha(r_j) \beta(R_{v0[i]} \) an effort estimation is done by computing \( \text{eff}(\mathcal{R}') \). The set of requirements is feasible if and only if \( \text{eff}(\mathcal{R}') \leq \text{EFFORT} \). If the set is not feasible, the procedure terminates by application of procedure \( \text{RSS}(\mathcal{R}') \) for computing the set \( \Gamma \) of non-dominated solutions.

6. VALIDATION OF THE APPROACH USING ‘GENSIM’

We validate the proposed approach by considering the development of a software product that has three classes of users: novice (\( S_1 \)), advanced (\( S_2 \)), and expert (\( S_3 \)) users. Typically, for a product, e.g., a text processing software system, different classes of users have different requirements on the key features of that product. We assume an original set of ten requirements where each requirement belongs to one of the three classes of requirements \( R_1, R_2, \) and \( R_3 \). As the project progresses, two additional requirements \( r_{11} \) and \( r_{12} \) arise. The three classes correspond to three different categories of requirements:

- Performance (class \( R_1 \))
- Usability (class \( R_2 \))
- Security and reliability (class \( R_3 \))

We use GEN SIM as introduced in section 4 to model and simulate this example. Basic information about the example and the results of three iterations are summarized in Table 2. Initially, ten requirements are taken into account. Later, two more requirements \( r_{11}, r_{12} \) are added. Columns \( \alpha(r_j) \), \( \beta(R_{v0[i]} \), and \( \chi(r_j) \) describe the relative importance of requirement \( r_j \) within class \( R_{vi} \), importance of class \( R_{vi} \), and global importance of requirement \( r_j \), respectively. The two final rows of the table give the effort estimation \( \text{eff}(\mathcal{R}') \) of set \( \mathcal{R}' \) and the business value \( \Sigma \chi(r_j) \) associated with \( \mathcal{R}' \).

The total effort available to implement the final set of requirements is \( \text{EFFORT} = 4300 \) person days. The development process, manpower size and experience are fixed, as well as the product quality. Each requirement is assumed to have a fixed size and specific complexity (e.g., low, medium or high). System dynamics gives an estimate of the total effort required for the implementation of each subset of requirements.

We assume the product manager has to decide which of the initially given ten (later, this will be twelve) requirements will be selected to maximize the overall business value (step 1). For that purpose, \( s \) defines a 3x3-matrix \( M^0 \) of preferences between the three types of users in terms of the overall goal to maximize the business value. Matrices \( M^1, M^2, \) and \( M^3 \) describe the preferences of the three classes of requirements (i.e., \( R_1, R_2, R_3 \)) from the perspective of stakeholder \( S_1, S_2, \) and \( S_3 \), respectively (see Figure 1). This may look as follows:

\[
M^0 = \begin{bmatrix}
1 & 3 & 6 \\
\frac{1}{3} & 1 & 4 \\

\]
R3) for the overall business value (step 4): WinWin.

The AHP analysis gives us vectors of eigen-values. They are denoted by weight0, weight1, weight2, and weight3, respectively.

- weight0 = (0.644, 0.271, 0.085) gives the importance of the three stakeholders (i.e., novice, advanced, expert) for the final business value from the perspective of the product manager (step2).
- weight1 = (0.570, 0.333, 0.097) gives the importance of the three classes of requirements (i.e., R1, R2, R3) from the perspective of the novice user (step3.1).
- weight2 = (0.100, 0.300, 0.600) gives the importance of the three classes of requirements from the perspective of the advanced user (step 3.2).
- weight3 = (0.117, 0.683, 0.200) gives the importance of the three classes of requirements from the perspective of the expert user (step3.3).

The consecutive application of the weights computed in steps 2 and 3 results in β = (β(R1), β(R2),…, β(R3)) which is the vector of importance of the three classes of requirements (i.e., R1, R2, R3) for the overall business value (step4):

\[
\begin{align*}
\text{Iteration 1:} & \quad (R1) \begin{bmatrix} 0.5700.3330.097 \end{bmatrix} \\
\text{Iteration 2:} & \quad (R2) \begin{bmatrix} 0.1000.3000.600 \end{bmatrix} \\
\text{Iteration 3:} & \quad (R3) \begin{bmatrix} 0.1170.6830.200 \end{bmatrix}
\end{align*}
\]

According to the individual scorings, the first class of requirements is most important, and the second class is the least important one. Eventually, these scores could be changed as part of the stepwise refinement approach. However, we will not consider such changes in this example.

To illustrate the concept of stepwise refinement, we assume three iterations. At each iteration, the requirements acceptance threshold is increased. In order to simplify the example, we assume that the preference in AHP described by the four 3x3-matrices does not change over time. As stated above, this is not a necessary prerequisite for the applicability of Quantitative WinWin.
4300=EFFORT. We systematically search for all those requirements, if eliminated from $\mathbb{R}^2$, would result in a new subset satisfying the effort constraint. As a result of this procedure, we obtain non-dominated solutions $\mathbb{R}^{3\times 2}$ with the property that improvement in one dimension (less effort or higher business value) can only be achieved by worsening the other. The trade-off curve between estimated effort and associated business value is shown in Figure 4. Two solutions $\mathbb{R}^{3\times 2}$ and $\mathbb{R}^{3\times 2}$ are offered in correspondence to the two shaded columns in Table 2. In general, decision support is considered to offer a small set of candidate non-dominated solutions that are used to choose the final one taking into account all implicit context factors.

7. SUMMARY AND CONCLUSIONS

One of the limitations of the Easy WinWin model is that negotiation is based on subjective measures. Which alternative will be chosen is a decision to be made by the project manager based on more or less accurate estimates. What is missing is a sound, quantitative evaluation of alternatives. In this paper, we have described a new and promising approach to support decision-making in the context of requirements selection. The added value of the Quantitative WinWin approach is its ability to offer quantitative analysis as a backbone for actual decisions. The application of Quantitative WinWin helps in the selection of requirements that meet the key needs of the most important stakeholders while still staying within the cost constraints and the required time-to-market.

The approach has been initially validated using a small-scale example with industrial data for modelling and simulation. However, the scalability of the approach still needs to be tested using a larger set of requirements. Main risks of the overall approach are (i) the availability of a sound and sufficiently detailed model for the estimation of total effort, and (ii) the availability and cooperation of stakeholders for eliciting their preference portfolio. There is a strong dependency between the quality of these two contributions and the applicability of the approach.

The presented results are part of a larger research effort on Software Engineering decision support [18]. Future research in this area will be devoted to extend the current model in terms of more sophisticated (time and effort dependent) effort constraints. In addition to that, other constraints than effort such as reliability or maintainability could be included. Finally, the full power of the underlying simulation capabilities could be used to study even more solution alternatives by varying the input parameters described in Table 1 and by defining additional parameters.

8. ACKNOWLEDGMENTS

The authors would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC), the Alberta Software Engineering Research Consortium (ASERC) as well as the Alberta Informatics Circle of Research Excellence (iCORE) for their financial support of this research. Many thanks also to Tatyana Krivobokova for improving the GENSIM model and Trevor Croft for conducting numerical analysis using AHP.
