Abstract

The Si-rich silicon oxide (SiO_x) thin films are prepared on silicon crystalline substrates by low pressure chemical vapor deposition (LPCVD) method. The oxygen concentration x are controlled by the ratio of the partial pressures of N_2O and SiH_4 gases in the reaction chamber. In order to induce the phase separation on SiO_2 and Si nanostructures the samples are annealed at the temperatures 900–1100 °C. The structural and optical properties of the samples are investigated by Raman and infrared spectroscopy and scanning electron microscopy.

Keywords: Si-rich silicon oxide; LPCVD; Raman scattering; Low frequency particle modes

1. Introduction

The growth of thin films by low pressure chemical vapor deposition (LPCVD) is one of the most important techniques for deposition of thin films in modern technology. The reasons of a broad application of the LPCVD method are in possibility of deposition of different elements and compounds at relatively low temperatures in amorphous and crystalline phase with high degree of uniformity and purity. A simple handling, high reliability of operations, fast deposition, homogeneity of deposited layers and high reproducibility are the basic characteristics the LPCVD method.

Apart from vitreous silica as the archetypal oxide network former and the basis of traditional silicate glasses other amorphous oxides of silicon such as silicon monoxide and silicon sesquioxide (Si_3O_4) also exists. These amorphous silicon suboxides have been known for decades and are used in a variety of technical applications. The possibility of phase separation of silicon suboxides into silicon and SiO_2 was first proposed by Brady [1]. On the basis of a theoretical approach this concept was discussed in more detail by Temkin [2] who proposed a random-mixture (RM) model. The RM model assumes small domains in which either silicon is bonded only to silicon or to oxygen. This corresponds to a two-phase mixture of Si and SiO_2 domains with thin boundary layer of ≈10 Å between [2].

Dupree et al. [3] performed magic-angle spinning (MAS) NMR investigations on silicon monoxide and estimated phase separated regions of Si and SiO_2 near to 20 Å.

In this paper we show the results of the LPCVD deposition of non stoichiometric oxide SiO_x thin films with SiH_4 and N_2O precursors. The chemical reaction we used is...
oxidation of silane with N\textsubscript{2}O: SiH\textsubscript{4} + γN\textsubscript{2}O \rightarrow p-SiO\textsubscript{x} + (1 - p)SiH\textsubscript{4} + 2pH\textsubscript{2} + (γ - px)N\textsubscript{2}O + px N\textsubscript{2}. The silicon nanocrystals were formed by phase separation of SiO\textsubscript{x} (x < 2) structure induced by thermal annealing: SiO\textsubscript{x} \rightarrow (1 - x/2) Si + x/2 SiO\textsubscript{2}, where N\textsubscript{2}O/SiH\textsubscript{4} ratio controls the Si amount in the layer.

2. Experimental

The LPCVD method is most successfully applied in deposition of polysilicon thin films from SiH\textsubscript{4} in the temperature range 580–660 °C and SiO\textsubscript{2} layers from SiH\textsubscript{2}Cl\textsubscript{2} at 900 °C. The scheme of the conventional hot-wall horizontal LPCVD reactor is shown in Fig. 1. The base of device is a quartz tube placed in a spiral heater. The tube is evacuated on the pressure of 0.1 Pa and heated on to the wanted temperature to 1000 °C. The temperature stability is ±1 °C. The deposition starts with entering of the working gas in the tube. The working (dynamical) pressure is 10–200 Pa.

In this experiment the non-stoichiometric oxide SiO\textsubscript{x} (x < 2) were deposited on a (111) oriented silicon substrate with a diameter of 50 mm set at 7 mm from the 1st (dummy) wafer. The depositions were carried out by thermal decomposition of 2% (S1) and 26% silane (S2 and S3) diluted in argon. The deposition temperatures were 748 °C. The flow rate ratios of nitrous oxide and silane \(\Phi(N_2O)/\Phi(SiH_4)\) are presented in Table 1. The SiO\textsubscript{x} films were further thermally annealed at 900, 1000 and 1100 °C in air. Upon annealing the decomposition of SiO\textsubscript{x} into SiO\textsubscript{2} and elemental Si takes place. After the decomposition, the excess Si atoms form Si clusters embedded in a SiO\textsubscript{2} matrix. The size of Si clusters is expected to become larger for the higher annealing temperatures. The deposited layers were characterized by Raman spectroscopy using Dilor Z-24 Raman triple monochromator spectrometer, IR absorption spectroscopy and scanning electron microscopy (SEM).

3. Results and discussion

The main difference between CVD depositions at low pressure and atmospheric pressure is in ratio of the mass transport velocity and the velocity of reaction on the surface. At atmospheric pressure these quantities are of the same order of magnitude. While the velocity of the mass transport depends mainly on the reactant concentration, diffusion, and thickness of the border layer, the velocity of the surface reaction depends mainly on the concentration of reactants and temperature. As diffusion of gas is reciprocal to pressure, it will decrease 1000 times if the pressure reduces from atmospheric value to 100 Pa. Now the carrier gas is not more necessary, the substrates could approach more closely, and deposited films shows better uniformity and homogeneity. The working gas, that regularly consist of the gas for dilution and of the reactive gas, after entering spreads inside the tube and flows above the hot substrates (thin wafers of silicon, quartz or some other material) placed in the quartz holders. The wafers in the tube reactor are radiantly heated by resistive hearing coils surrounding the tube. The critical factors that influence on thickness uniformity and film content are positions of the substrates, temperature profile in the zone of deposition, reactor geometry, deposition time, working pressure, as well as the quantity and content of all gases or vapors that enter in the reactor.

Fig. 2a shows the FTIR spectrum of the sample S1. The band above 1000 cm\textsuperscript{-1} is assigned to the asymmetric stretching of the Si–O–Si bridge. This peak position can be used for reasonable stoichiometry estimation in case of a homogeneous SiO\textsubscript{x} alloy [4]. The observed peak position at 1072 cm\textsuperscript{-1}, which differs from the position of thermally grown oxide at ~1080 cm\textsuperscript{-1}, gives the composition \(x = 1.9\). The SEM image in Fig. 2b shows that the layer is porous and inhomogeneous. These results show that the structure of deposited layer is more close to the silica structure than to SiO\textsubscript{2} structure.

In order to decrease the composition \(x\) we have decreased the flow rate ratio to: \(\Phi(N_2O)/\Phi(SiH_4) = 1.14\) (sample S2). Fig. 3 shows the Raman spectra of as deposited and annealed samples. The Raman spectra shows the characteristic bands of SiO\textsubscript{x} structure that consists of the broad peaks at 160 and 460 cm\textsuperscript{-1} which corresponds to the TO and TA phonon-like bands. Upon thermal annealing the decomposition of SiO\textsubscript{x} into SiO\textsubscript{2} and elemental Si
takes place. After decomposition, the excess Si atoms form Si clusters embedded in a SiO$_2$ matrix. The size of Si clusters is expected to become larger for higher annealing temperatures. The Raman scattering on nanosized silicon particle manifests in broadening and red shift of the TO($\Gamma$) phonon band at 521 cm$^{-1}$ and blue shift of the low frequency spherical mode with decrease of particle size. The model of phonon confinement of optical modes [5] and the calculation of spherical acoustical modes are applied in order to deduce the mean size and distribution width of silicon nanocrystals [6].

Low frequency modes indicated by an arrow in Fig. 3b corresponds to the spherical acoustical modes of silicon nanocrystals. Vibrations of elastic spheres have been studied for a long time by Lamb [7]. The frequency (in wave numbers) of the symmetric spherical mode is given by [8]:

$$v_0 = \frac{S_0 v_L}{cD},$$  \hspace{1cm} (1)

where $v_0$ is the frequency of the symmetric mode, $D$ is the diameter of the spherical particle and $c$ is the velocity of light. The constant $S_0 = 0.76$ [6]. The mean value of the longitudinal sound velocities calculated across three crystalline directions is $v_L = 8790$ m/s. These parameters when inserted in Eq. (1) give the mean size of silicon nanoparticles from the know frequency of the symmetric spherical mode, i.e. $D = 2.29 \times 10^{-7}/v_0$. Experimentally, by comparison of the low frequency Raman results with the particles size distributions obtained by TEM, the size of silicon particles deduced by Eq. (1) are by the factor of 0.5 smaller [6]. The reason for such factor is still unclear and could be connected with the resonance phenomena of incident laser
energy with the exciton transition in silicon [6]. Taking this into the consideration, the silicon nanocrystals with mean sizes of 3.2, 5.2 and 8.8 nm are formed in the films annealed at 900, 1000 and 1100 °C, respectively. Some broad bands with maximum at 54 cm\(^{-1}\) also exist for the as deposited samples. This could be also ascribed to spherical vibrations that correspond to the broad distribution of silicon nano-particles. The mean particles size of 2.2 nm estimated from the peak maximum agree with the value obtained by NMR measurements of Dupree et al. [3].

With further decrease of the flow rate ratio to \(\Phi(N_2O)/\Phi(SiH_4) = 1.03\) (sample S3), the black porous structure with porous surface morphology shown in Fig. 4 is obtained. The sample is than further annealed at 900 °C for 1 h in air. The low frequency Raman spectra of the as deposited and annealed sample shows the broad peaks of spherical modes with maximums at 43 and 50 cm\(^{-1}\) which corresponds to the mean particle size of 2.7 and 2.3 nm, respectively. The existence of such small crystallites are also confirmed by the Raman scattering on the confined TO(\(\Gamma\)) phonon mode that appear as a shoulder and sharp peak at 509 cm\(^{-1}\) of the as prepared and annealed sample. By applying the phonon confinement model, the mean particle size is possible to obtain by the relation [5]: \(D = \frac{0.337}{(521/v-1)}\), where \(v\) is observed frequency of TO(\(\Gamma\)) phonon mode. The particles of mean size of 1.4 nm were found by this formula which is similar to those found from the LFR modes Fig. 5.

As a conclusion here we have shown that by using LPCVD technique a number of different silicon \(SiO_x\) nano-structures important for microelectronic and photonic application is possible to prepare with rather simple approach. The content of oxygen atoms is possible to control by of nitrous oxide and silane partial pressure gas ratio and the particle size by the temperature of annealing process. The different size of silicon nanocrystals in silica matrix are obtained by subsequent annealing of \(SiO_x\) structure. The Raman scattering techniques showed to be simple and reliable technique in determination of size of prepared silicon nanoparticles.
