Abstract—Primary users (PU) separation concerns with the issues of distinguishing and characterizing primary users in cognitive radio (CR) networks. We argue the need for PU separation in the context of collaborative spectrum sensing and monitor selection. In this paper, we model the observations of monitors as boolean OR mixtures of underlying binary latency sources for PUs, and devise a novel binary inference algorithm for PU separation. Simulation results show that without prior knowledge regarding PUs’ activities, the algorithm achieves high inference accuracy. An interesting implication of the proposed algorithm is the ability to effectively represent \( n \) independent binary sources via (correlated) binary vectors of logarithmic length.

I. INTRODUCTION

With the ongoing growth in wireless services, the demand for the radio spectrum has significantly increased. However, the spectrum resources are scarce and most of them have been already licensed to existing operators. Recent studies have shown that despite claims of spectral scarcity, the actual licensed spectrum remains unoccupied for long periods of time [1]. Thus, cognitive radio (CR) systems have been proposed [2], [3], [4] in order to efficiently exploit these spectral holes. CRs or secondary users (SUs) are wireless devices that can intelligently monitor and adapt to their environment, hence, they are able to share the spectrum with the licensed primary users (PUs), operating whenever the PUs are idle.

One key challenge in CR systems is spectrum sensing, i.e., SUs attempt to learn the environment and determine the presence and characteristics of PUs. Spectrum sensing can be done at SUs individually or cooperatively [5], [6], with or without the assistance of infrastructure supports such as dedicated monitor nodes and cognitive pilot channel (CPC) [7], [8], [9], [10]. At individual nodes, energy detection is commonly adopted to detect the presence of PUs, in which the detector computes the energy of the received signal and compares it to a certain threshold value to decide whether the desired signal is present or not. Energy detection has the advantage of short detection time but suffers from low accuracy compared to feature-based approaches such as cyclostationary detection [3], [4]. From the perspective of a CR system, it is often insufficient to detect whether a PU activates in a single SU’s vicinity (“is there any PU near me?”). Rather, it is important to determine the identity of PUs (“who is there?”) as well as the distribution of PUs in the field (“where are they?”). We shall call these issues the PU separation problem.

To motivate the need for PU separation, let us consider the following scenarios:

- Multiple SUs cooperatively infer the activities of PUs, some of which may be observable to only a subset of SUs. In this case, the SUs need to identify the PU-SU adjacency relationships. Blindly assuming all PUs are observable to all SUs would lead to inferior detection results.
- Dedicated monitors are employed for spectrum sensing. There exists redundancy in monitors’ observations due to common PUs across multiple monitors. Such redundancy can be reduced by judiciously selecting a subset of monitors to report their spectrum sensing results. Furthermore, some monitors can be put to low-power modes for energy conservation.

Clearly, PU separation is a more challenging problem compared to node-level PU detection. The conventional wisdom would be that sophisticated methods such as feature-based detection are necessary. On the contrary, we find that through cooperation among monitors or SUs, not only the accuracy of energy detection can be improved as been demonstrated in several existing work, interestingly, PUs can be identified using solely binary information (due to thresholding in energy detection). The key to this somewhat surprising result is a binary inference framework that models the observations of SUs and monitors as boolean OR mixtures of underlying binary latency sources for PUs. It allows us to exploit the correlation structure among distributed binary observations.

We develop an iterative algorithm, called Boolean Independent Component Analysis (bICA), to determine the underlying latent sources (i.e., PUs) and their active probability. In bICA, no prior information regarding the PUs’ activities or observation noise is assumed. Given \( m \) monitors or SUs, up to \( 2^m - 1 \) PUs can be inferred resulting in great efficiency. This is analogous to compressive sensing techniques [11], [12], where sub-Nyquist sampling rates are sufficient for spatially sparse data. Evaluation results show the effectiveness of bICA under realistic settings.

The rest of the paper is organized as follows. In Section II the observation model is introduced. In Section III we present
the bICA algorithm to determine the statistics of PU activities and the inference algorithm to decide which set of PUs are active. Evaluation results are detailed in Section IV followed by conclusions and future work in Section VI.

II. Model and Preliminaries

Consider a slotted system where the transmission activities of $n$ PUs are modeled as a set of independent binary variables $y$ with active probabilities $\mathcal{P}(y)$. The binary observations due to energy detection at the $m$ monitor nodes (for the remaining of the paper, we do not distinguish monitor nodes and SUs) are modeled as an $m$-dimension binary vector with joint distribution $\mathcal{P}(x)$. It is assumed that the presence of any active PU in the surrounding of a monitor leads to positive detection. An (unknown) binary mixing matrix $G$ is used to represent the relationship between the observable variables in $x$ and the latent binary variables in $y = [y_1, y_2, \ldots, y_n]$ as follows:

$$x_i = \bigvee_{j=1}^{n} (g_{ij} \land y_j), \quad i = 1, \ldots, m,$$  \hfill (1)

where $\land$ is Boolean AND and $\lor$ Boolean OR, and $g_{ij}$ the entry in the $i$th row and $j$th column of $G$. For the ease of presentation, we introduce a short-hand notation as

$$x = G \oplus y.$$  \hfill (2)

In essence, $g_{ij}$ encodes whether monitor $i$ can detect the transmissions of PU $j$. For a monitor $i$, the energy detection returns 1 when one or more of the PUs that the monitor can detect are active. $G$ can be thought of as the adjacency matrix of an undirected bi-partite graph $G = (U, V, E)$, where $U = \{x_1, x_2, \ldots, x_m\}$ and $V = \{y_1, y_2, \ldots, y_n\}$ (Figure 1). An edge $e = (x_i, y_j)$ exists if $g_{ij} = 1$.

Consider a matrix $m \times T$ matrix $X$, which is the collection of $T$ realizations of vector $x$. The goal of binary independent component analysis (bICA) is to determine the latent independent random variables $y$ and the binary mixing matrix $G$ from $X$ such that $X$ can be decomposed into the mixing of realizations of $y$. From $G$ and $y$, we can identify the PUs via the set of monitors, to which they are observable, and additionally infer the active probability of PUs.

Note that the above model differs from blind deconvolution with binary sources [13] in that in bICA, the mixing matrix is binary, and the mixtures are generated from OR operations instead of linear transforms over binary sources. Independent component analysis (ICA) has been studied in the past as a computational method for separating a multivariate signal into additive subcomponents supposing the mutual statistical independence of the non-Gaussian source signals. Most ICA methods assume linear mixing of continuous signals [14].

III. Binary Inference Framework

In this section, we first discuss the identifiability of binary independent sources for PUs from OR mixtures observed at the monitors, and then present an inference algorithm that determines the unknown mixing matrix and underlying sources.

![Figure 1: Illustration of Monitors’ Observations of PU](image)
B. The inference algorithm

Before proceeding to the details of the algorithm, we first present a few technical lemmas.

Lemma 1: Consider a set \( x = [x_1, x_2, \ldots, x_{k-1}, x_k] \) generated by the data model in (1), i.e., \( \exists \) binary independent sources \( y \), s.t. \( x = G \oplus y \). The conditional random vector \( x_{x_k=0} = [x_1, x_2, \ldots, x_{k-1} | x_k = 0] \) corresponds to realizations of \( x \) when \( x_k = 0 \). Then, \( x_{x_k=0} \) is \( G' \oplus y' \), where \( G' = G_{1:2^k-1} \) and \( \mathcal{P}(y'_l = 1) = \mathcal{P}(y_l = 1) \) for \( l = 1, \ldots, 2^k - 1 \).

Proof:

\[
\mathcal{P}(x_k = 0) = \prod_{g_k=0} (1 - p_l), \text{ we have} \]

\[
\mathcal{P}(y'_l = 1) = \mathcal{P}(y_l = 1) \quad \text{for} \quad l = 1, \ldots, 2^{k-1}, \text{ the above equality holds. In another word, the conditional random vector} \quad x_{x_k=0} = G' \oplus y' \text{ for} \quad G' = G_{1:2^k-1}.
\]

The above lemma establishes that the conditional random vector \( x_{x_k=0} \) can be represented as an OR mixing of \( 2^k-1 \) independent components. Furthermore, the set of the independent components are the same as the first \( 2^k-1 \) independent components of \( x \) (under proper ordering).

Consider a sub-matrix of the data matrix \( X_k \), \( X_{(k-1)}^T \) where the rows correspond to observations of \( x_1, x_2, \ldots, x_{k-1} \) for \( t = 1, 2, \ldots, T \) such that \( x_{kt} = 0 \). Define \( X_{(k-1)}^T \), which consists of the first \( k-1 \) rows of \( X_k \). Suppose that we have computed the BICA for data matrices \( X_{(k-1)}^T \) and \( X_{(k-1)}^T \). From Lemma [1], we know that \( X_{(k-1)}^T \) is realization of OR mixing of independent components, denoted by \( y_{k-1}^0 \). Furthermore, \( \mathcal{P}(y_{k-1}^0(l) = 1) = \mathcal{P}(y_l = 1) \) for \( l = 1, \ldots, 2^{k-1} \). Clearly, \( X_{(k-1)}^T \) is realization of OR mixing of independent components, denoted by \( y_{k-1}^1 \) (* for do not care). Additionally, it is easy to see that the following holds:

\[
\mathcal{P}(y_{k-1}^1(l) = 1) = 1 - (1 - \mathcal{P}(y_{k-1}^0(l) = 1))(1 - p_{l+2^{k-1}})
\]

where \( l = 1, \ldots, 2^{k-1} - 1 \). Therefore,

\[
p_l = \mathcal{P}(y_{k-1}^0(l) = 1) \quad l = 1, \ldots, 2^{k-1}
\]

\[
p_{l+2^{k-1}} = 1 - \mathcal{P}(y_{k-1}^0(l) = 1) \quad l = 1, \ldots, 2^{k-1}
\]

\[
p_{2^{k-1}} = \frac{\mathcal{P}(x_1 = 1 \land x_2 = 0, \forall \ell \in [0 \ldots 2^{k-1}])}{\Pi_{1 \leq i \leq 2^k-1} (1 - p_\ell)}
\]

The last equation above is due to the fact that observations where \( x_k = 1 \) while \( x_i = 0 \) for \( i = 0, \ldots, k-1 \) are the result of active \( y_{2^{k-1}} \). Define \( \mathcal{F}(x) \) as the frequency of the random vector \( x \) from the data matrix \( X \). To this end, we have the following iterative algorithm as illustrated in Algorithm [1].

**Algorithm 1**: Incremental Binary ICA inference algorithm

**Computation complexity**: Let \( S(m) \) be the computation time for finding BICA given \( X_{m \times T} \). From Algorithm [1] we have,

\[
S(m) = 2S(m-1) + c2^m,
\]

where \( c \) is a constant. It is easy to verify \( S(m) = cm2^m \). Therefore, Algorithm [1] has an exponential computation complexity with respect to \( m \). This is clearly undesirable for large \( m \)’s. However, we notice that in practice, correlations among \( x_i \)’s exhibit locality, and the \( G \) matrix tends to be sparse. Instead of using a complete bipartite graph to represent \( G \), the degree of vertices in \( V \) (or the number of non-zero elements in \( g_{ij} \)) tend to be much less than \( m \). More specifically, for every pair \( i \) and \( k \), compute

\[
\text{Cov}(i, k) = \frac{\sum_{t=1}^T X_{it}X_{kt}}{T} - \frac{\sum_{t=1}^T X_{it}\sum_{t=1}^T X_{kt}}{T}.
\]

If \( \text{Cov}(i, k) < \epsilon \), where \( \epsilon \) is a small value (e.g., upper confidence bound of \( \text{Cov}(i, k) \) estimate), we can remove the corresponding columns in \( G \) and elements in \( y \).

IV. Evaluation

In this section, we first introduce the performance metrics and then present evaluation results on a synthetic data set with varying number of PUs.
A. Performance metrics

Denote \( \hat{p} \) and \( \hat{G} \) the inferred PUs’ active probabilities and the mixing matrix, respectively. Note that order of PUs in the inferred model may be different from that in the original model. To measure the closeness of the inferred model with the ground truth, we first select the top \( n \) (with highest probability) components of the inferred model and remove the remaining columns in \( \hat{G} \), where \( n \) is number of PUs. Then, we permute columns of \( G \) (corresponding to different PUs) such that a good match between \( \hat{G} \) and \( G \) can be found. Full details of the problem above, namely Bipartite Graph Matching Problem, will be reported in our future publication. Once the ordering in \( \hat{G} \) is decided, active probabilities are compared.

To evaluate performance of the proposed algorithm, we introduce the following two metrics.

- **Normalized Hamming Distance:** This metric measures accuracy of the inferred mixing matrix defined as the Hamming distance between \( G \) and \( \hat{G} \) divided by the size of \( G \).
  \[
  H = \frac{1}{mn} \sum_{i=1}^{m} \sum_{j=1}^{n} |\hat{g}_{ij} - g_{ij}|. \tag{7}
  \]
  Clearly, the smaller the \( H \) the better.

- **Root Mean Square Error Ratio (RMSE Ratio):** RMSE Ratio measures the deviation of inferred PU activities from original values.
  \[
  \hat{P} = \sqrt{\frac{\sum_{i=1}^{n} (\hat{p}_{i} - p_{i})^2}{\sum_{i=1}^{n} p_{i}}}. \tag{8}
  \]

B. Experimental results

10 monitors and \( n \) PUs are deployed in an 1000x1000 square meter area, with \( n \) varying from 5 to 20. Locations of PUs are chosen arbitrarily with the restriction that no two PUs can be observed by the same set of monitors. The PUs’ transmit power is 20mW, the noise level is -70dbm, and the propagation loss factor is 3. The SNR threshold for monitors to detect primary users is 5dB. Elements in the binary mixing matrix \( G \) are either 1 or 0, depending whether or not received signals are higher than the threshold. PUs’ activities are modeled as a two-stage Markov chain with transition probabilities uniformly distributed over \([0,1]\). A monitor reports the channel occupancy if any detectable PU is active. Number of monitors’ observations \( T \) is 10,000.

One example scenario with 10 PUs is illustrated in Fig. 2 and the inferred result is available in Fig. 3. Non-zero entries and zero entries of \( G \) and \( \hat{G} \) are shown as black and white dots, respectively. The entry-wise difference matrix \( |G - \hat{G}| \) is given in the bottom graph. In this case, only the first row (corresponding to the first monitor) contains some errors.

We have implemented our algorithm in Matlab. All experiments are conducted on a workstation with an Intel Core 2 Duo T5750@2.00GHz processor and 2GB RAM. Experiment results over 20 runs for each PU setting are shown in Fig. 4. At zero noise, we observe that the inferred mixing matrix \( G \) is mostly correct even for a large number of PUs (Fig. 4(a)). As the number of PUs increases, errors in the inferred active probabilities tend to increase though within 10% on average as shown in Fig. 4(b). Recall that PUs are ordered based on their respective columns in \( G \). Therefore, errors in \( \hat{G} \) may have a cascading effect since we may compare the wrong pair of PUs as a result. And when we increase noise level to 2% and 5%, average error rate raises to 10%, 20% on \( G \) and 30%, 60% on \( p \) respectively. Apparently our method is quite sensitive to noise. From Fig. 4(c), we see the computation time is negligible (under 0.2 second) at zero noise. With the introduce of noise, computation time increases but is approximately equal at different noise levels. This simply because our complexity reduction technique were disabled. Due to space limit, experimental results with varying numbers of samples \( T \) are omitted. We observe that having more samples beyond 10,000 has marginal impact on the accuracy of the inference.

V. RELATED WORK

Most ICA methods assume linear mixing of continuous signals \([14]\). A special variant of ICA, called binary ICA, considers boolean mixing (e.g., OR, XOR etc.) of binary signals. Existing solutions to BICA mainly differ in their
assumptions of prior distribution of the mixing matrix, noise model, and/or hidden causes. In [15], Yeredor considers BICA in XOR mixtures and investigates the identifiability problem. A deflation algorithm is proposed for source separation based on entropy minimization. In [15] the number of independent random sources $K$ is assumed to be known. Furthermore, the mixing matrix is an $K$-by-$K$ invertible matrix. In [16], infinite number of hidden causes following the same Bernoulli distribution are assumed. Reversible jump Markov chain Monte Carlo and Gibbs sampler techniques are applied. In contrast, in our model, the hidden causes may follow different distribution and the mixing matrix tends to be sparse. Streith et al. [17] study the problem of multi-assignment clustering for boolean data, where the observations either draw from a signal following OR mixtures or from a noise component. The key assumption made in this work is that elements of the matrix $X$ are conditionally independent given the model parameters. This greatly reduces the computational complexity and makes the scheme amenable to gradient descent optimization solution this assumption is in general invalid. In [18], the problem of factorization and de-noise of binary data due to independent continuous sources is considered. The sources are assumed to be following beta distribution. Finally, [19] consider under-presented case of less sensors than sources with continuous noise, while [18], [17] deals with over-determined case, where number of sensors are much larger. In this work, we consider primarily the under-presented cases encountered in data networks.

VI. Conclusion

In this paper, we propose a binary inference framework for PU separation in cognitive radio networks. Simulation results show the proposed algorithm can achieve less than 4% error in the inferred mixing matrix and less than 10% error for the active probability of PUs. PUs can thus be seperated based on the set of monitors to which they are observable. As ongoing work, we are investigating effect of noise on the inference accuracy and aiming to develop a robust inference framework.
